Environmental contaminants from land to sea: continuities and interface in environmental toxicology and chemistry

Nantes 2016
SETAC Europe

ABSTRACT BOOK
SETAC Europe 26th Annual Meeting

TABLE OF CONTENTS

Keynote abstracts	3
Platform abstracts	4
Poster abstracts	131
Poster corner abstracts	351
Keyword index	363
Author index	368

This book composes the abstracts of the presentations for the platform and poster sessions of the 26th Annual Meeting of the Society of Environmental Toxicology and Chemistry (SETAC), conducted at La Cité Nantes Congress Center in Nantes, France, from 22 - 26 May 2016. The abstracts are reproduced as accepted by the Scientific Committee of the meeting and appear in order of abstract code, in alphabetical order per presentation type. The poster spotlight abstracts are included in the list of poster abstracts. The presenting author of each abstract is underlined.

SOCIETY OF ENVIRONMENTAL TOXICOLOGY AND CHEMISTRY

In the 1970s, no forum existed for interdisciplinary communication among environmental scientists, biologists, chemists, toxicologists as well as managers and engineers others interested in environmental issues. The Society of Environmental Toxicology and Chemistry (SETAC) was founded in North America in 1979 to fill the void. Based on the dynamic growth in the Society's membership, meeting attendance and publications, the forum was clearly needed. SETAC has two administrative offices, in Pensacola, Florida, USA, established in 1990, and in Brussels, Belgium, established in 2003.
A unique strength of SETAC is its commitment to balance the scientific interests of government, academia and business. The Society by-laws mandate equal representation from these three sectors for officers, World Council, Geographic Unit Boards of Directors and Councils, and Committee members and governance of activities. The proportion of members from each of the three sectors has remained nearly equal over the years.
SETAC publishes two globally esteemed scientific journals and convenes annual meetings around the world, showcasing cutting-edge science in poster and platform presentations. Because of its multidisciplinary approach, the scope of the science of SETAC is broader in concept and application than that of many other societies.
The Society is concerned about global environmental issues. Its members are committed to Environmental Quality through Science®, to timely and effective communication of research, and to interactions among professionals so that enhanced knowledge and increased personal exchanges occur. SETAC's growth has been marked the establishment of geographic units around the world: SETAC Europe in 1989, SETAC Asia/Pacific in 1997, SETAC Latin America in 1999 and SETAC Africa in 2012. As evidence of international acceptance of the SETAC model and of the great interest at the local level, regional chapters of the geographic units are being considered for a number of countries.

Publications
Environmental Toxicology and Chemistry, an internationally acclaimed scientific journal, has grown from a quarterly publication of fewer than 400 pages annually in 1980 to a monthly publication of nearly 3,000 pages annually.
Integrated Environmental Assessment and Management, launched in 2005 to bridge the gap between scientific research and its application in environmental decision-making, regulation and management, has become a well-respected quarterly publication of 700 pages annually.
SETAC Books total more than 100, encompassing workshop results and other scientific studies.

Keynote Abstracts

K1
The Plastic Tide
Thomas Maes, Cefas, UK
BIO: Thomas Maes is a recognised science leader with nearly 10 years' experience in many aspects of coastal and ocean monitoring, ranging from chemical pollutants and related biological effects to marine litter and other emerging compounds. He has good interpersonal skills and is an effective communicator in different languages. Thomas is Cefas` International and National Monitoring Programme Coordinator who joined Cefas in 2008 after an international career as environmental manager for large marine development projects. He coordinates and develops Cefas` international monitoring programmes and provides advice to UK Government issues related to human activities such as contaminant and other emerging pressures. He is involved in the assessment of data and adaptation of monitoring programmes for further implementation of the MSFD. Thomas is currently also chairing the OSPAR monitoring and assessment group (MIME) and acting as the UK expert on Marine Litter in the European task groups. He manages large, multi-disciplinary research projects and monitoring programmes including leadership of several EU-funded programmes in relation to contaminants and marine litter (e.g.: MICRO, MARLISCO,...).

K2
Climate Change and Environmental Contamination by Chemicals: Do They Affect Ecological and Human Health?
Arja Rautio, Thule Institute, University of Oulu, Finland
New emerging contaminants, persistent organic pollutants (POPs) and toxic metals are transported to the Arctic from regions at lower latitudes. During the last twenty years the Arctic Monitoring and Assessment Programme (AMAP) has followed the levels of POPs and metals in environment, wild-life and human populations, especially pregnant women. Most POPs and metals are declining in many Arctic regions, but there are some areas and populations where levels remain high. Elevated concentrations of toxic metals (usually mercury) and environmental contaminants (dioxins and PCBs) have been measured in Greenland and Canada from seafood, like marine mammals and fish, and dietary advice is needed for users of traditional and local foods. Interactions between climate change and contaminant transport have the potential to change human exposure in the Arctic significantly. It is not possible to estimate the likelihood and magnitude of the health impacts and the changes in exposure.
The incidence of many Western type of diseases, like diabetes, heart diseases and cancers, has increased globally, and high increase in numbers have been found among people living in the Arctic. It has been assumed that environmental pollutants may have a contributing effect especially in some heavily exposed Indigenous populations. Epidemiological studies have shown the connections between contaminant exposure (especially mercury) and changes in foetal growth and child development and cardiovascular effects. However, investigations on the precise impact of environmental pollutants on human health are difficult to study, because there are many factors, which affect simultaneously and varying degrees. These include genetic background, age, sex, diseases, exposure history and environment. Environmental factors include mixtures of contaminants and other chemical compounds to which individuals are commonly exposed. Knowledge about the effects of mixtures is mainly missing and difficult to study at population level.
Exposure during the foetal period is in special attention in the epidemiological and mechanistic (in vitro) studies, because foetal stage is the most vulnerable during human life. During the last decade there have been several research projects under the framework of the EU, which have focused on potential toxicity at low exposure levels of environmental contaminants to child development (projects like ENRICO, OBELIX, CLEAR, INUENDO, ArcRisk, PHIME). One goal of this research has been to collect all the existing evidence about the associations between environmental contaminants and measured health outcomes. The evaluation of potential human health risks and their magnitude is needed.
Changes in climate, environmental and land use together with socioeconomic factors have impact on the contaminant exposure for wild-life and humans.

BIO: Arja Rautio, research professor, MD, PhD, Eurotox ERT, has been working in the field of circumpolar health since 2006 in the Thule Institute and Faculty of Medicine, University of Oulu, Finland. She is leading and participating in several national and international research projects, which focus on climate change, environmental health, risk assessment, and indigenous health and wellbeing. She is a chair of the University of the Arctic Thematic Network of Health and Wellbeing in the Arctic (www.uarctic.org), and is leading the international Master's and Doctoral programs on Circumpolar Health and Wellbeing. Dr Rautio is working as a national key expert in the Human Health Expert groups of the Arctic Monitoring and Assessment Programme (www.amap.no) and Sustainable Development Working Group (www.sdwg.org). She has been nominated as a national member to the International Arctic Science Committee - Social and Human Sciences Group (http://iasc.arcticportal.org). She is a chair of the Nordic Society of Circumpolar Health.

Environmental Assessment of Cosmetics and Personal Care Products: Challenges and opportunities
Marc Leonard, L'Oréal Advanced Research, France
Despite a frequent image of futility, cosmetic and personal care products provide strong societal benefits. For centuries, their use has been motivated worldwide by the continuing need for hygiene, beauty and self-esteem.
Nowadays, cosmetics and personal care products (CPCP) are most frequently used in the bathroom. After rinsing they flow down the drain where they mix with wastewaters. In industrialized countries they are directed to sewage treatment plants, but in many developing countries wastewaters may directly be discharged into rivers or the sea shore. In addition, certain products such as sunscreens may be directly released by swimmers in lakes, rivers or the ocean.
The exposure of the environment to cosmetic and personal care products is relatively low compared to contaminants from other industrial sectors but nonetheless, the environmental risk assessment of their constituents is done in a similar manner. Assessing their potential environmental impact faces significant methodology challenges because of their extremely diverse composition, from single ingredients to heterogeneous complex mixtures such as natural extracts and essential oils.
In parallel, there is a worldwide trend to move away from animal testing for the human and environmental safety assessment of cosmetics and personal care products. In this regard, fish which are key aquatic models in environmental risk assessment, fall into the scope of several international regulations for the protection of animals used for scientific purposes. As a consequence, replacing animal testing for the safety assessment of cosmetic and personal care products faces additional challenges when addressing environmental issues such as fish long term toxicity, environmental endocrine modulation and bioaccumulation, where fish BCF data are still required for regulatory PBT/vPvB classification.
Cosmetic companies share with authorities the desire to inform the public which products have the best environmental profile. Thus, several projects are under study at national (e.g. French) and international (e.g. EU) levels for consumer products environmental footprint labelling, including cosmetics and personal care products. They plan to assess the impact of products on aquatic ecosystems with the USEtox model, developed for Life Cycle Assessment (LCA). But some deviating results are obtained when using other methodologies such as the Critical Dilution Volume (CDV) calculation, which is required to award the European Ecolabel for cosmetics products. Concordant and relevant methodologies are needed and progresses are being made in this direction.
Nonetheless, this challenging context provides opportunities to develop alternative methodologies to anticipate potential short and long term adverse environmental effects of cosmetic and personal care products. Benefits are even expected from the field of human toxicology screening, where aquatic models such as the fish embryo are gaining much interest.
The purpose of this presentation will be to present the trends and advances in these fields.

BIO: Marc Leonard is presently head of L'Oreal Research & Innovation, Environmental Research Department. He obtained his doctorate in Veterinary Medicine from the Veterinary School of Maisons-Alfort (France), with a specialization in environmental toxicology from the Centre des sciences de l'Environnement - Metz University (France). The main activities of his department cover two domains : (1) Environmental Assessment of raw materials and cosmetic preparations with applied research aimed at developing cost-efficient assessment tests as potential alternatives to the corresponding OECD guidelines. Domains cover acute and chronic aquatic toxicity (soft and marine waters), bioaccumulation and biodegradation assessment. (2) Invertebrates and Fish Embryo models as potential alternative methods in Human Toxicology and Pharmacology.
He has been co-chairman of the HESI (Health & Environmental Sciences Institute) Committee on the Emergence of Animal Alternative Needs in Environmental Risk Assessment. He was member of the OECD Fish Embryo Toxicity Expert Group, and OECD Expert Group on Invertebrates Reproduction. He has hosted and co-organized several international workshops on the Fish embryo model with international partners such as HESI and UFZ (Helmotz Center) and contributed to publications in these fields.

Platform Abstracts

Contaminants of Emerging Concern in the Environment and their Management (I)

1
Solutions for present and future emerging pollutants in land and water resources management

Slobodnik, Environmental Institute; J. van Gils, DELTARES; A. van Wezel, KWR Watercycle Research Institute / Chemical Water Quality and Health
Despite significant efforts the good ecological status required by European Water Framework Directive (WFD) could not be achieved in the majority of European surface waters. Emerging pollutants such as pharmaceuticals, biocides, personal care products and many others are hypothesised to play a key role for water quality. The 5-year Collaborative Project SOLUTIONS addresses complex mixtures of potentially toxic compounds in the water cycle including legacy, presently used and future chemicals with monitoring-, modelling- and scenario-based approaches focusing on the assessment and prediction of the impact of these mixtures, on the identification of drivers of mixture toxicity focusing on deriving candidate River Basin Specific Pollutants (RBSPs) and on the identification of priority mixtures. For the identification of priority mixtures with respect to specific targets different criteria are used to establish chemical fingerprints based on common sources, modes of action, fate etc.. The impact of mixtures in the environment is addressed by the development and demonstration of a set of effect-based tools following the philosophy of adverse outcome pathways from key events on a molecular level via cellular and organism responses up to the community. These tools are evaluated and demonstrated in large scale case studies such as Rivers Danube, Rhine and Ebro. Results from the River Danube indicate low to moderate effects on a large range of endpoints, most of them explained only to a minor extent by target analytes. Prospective assessment using an integrated system of models and databases provides extensive predictions of concentrations and risks in the Danube river. First evaluations for individual chemicals such as PFOS and PFOA indicate good agreement between monitoring and modelling. Both approaches together are used to propose RBSPs.

2
Lagrangian tracer aided sampling approach in assessing the fate of wastewater-related contaminants in rivers
G. Guillet, Tübingen University / Applied Geoscience; J. Knapp, Eberhard Karls Universität Tübingen / Hydrogeology Center for Applied Geosciences; M. Schwientek, Eberhard Karls Universität Tübingen / Hydrogeochemistry Center for Applied Geosciences; S. Merel, Eberhard Karls Universität Tübingen / Environmental Analytical Chemistry Center for Applied Geosciences; O. Cirpka, Eberhard Karls Universität Tübingen / Hydrogeology Center for Applied Geosciences; C. Zwiener, Eberhard Karls Universität Tübingen / Environmental Analytical Chemistry Center for Applied Geosciences; P. Grathwohl, Eberhard Karls Universität Tübingen / Hydrogeochemistry Center for Applied Geosciences
Emerging contaminants are constantly released by Wastewater Treatment Plants (WWTPs) into surface waters. The persistence of these compounds influences how far they will spread within the river network, raising concern on the extent of their environmental impact and the issue for drinking water exploitations. To study the fate of wastewater-related pollutants in rivers, a common approach is using a Lagrangian sampling scheme. It consists in sampling the same parcel of water repeatedly as it flows along a selected river stretch. Where this approach allows monitoring concentration changes according to residence time, it may include uncertainties that can be misinterpreted as removal – diurnal pattern of WWTPs' effluent coupled with inaccurate travel time estimation and dispersion effects. A new sampling approach combining Lagrangian sampling with an artificial tracer was applied to study the fate of wastewater-related compounds in an impacted river segment. The tracer fluorescein was injected upstream of a 1,7 km long stretch of the Steinlach River, southwest Germany, downstream of a WWTP effluent. The segment was controlled by four measuring stations during a day and a night experiment. Normalizing the compounds concentrations to the tracer isn't possible in the context of wastewater-related compounds, constantly released unlike the tracer. Instead, breakthrough curves were deconvoluted to identify transfer functions between each measuring stations. Transfer functions were then applied to a concentration time series recorded by six 1h composite samples at the first sampling site. The obtained time series at each control plane were then compared to the concentration measured from a grab sample. Different behaviours from conservative to very reactive could be observed for the 43 investigated compounds. Compounds like the pharmaceuticals diclofenac or tramadol showed a strict photosensitive character. Other compounds were attenuated at a similar strength during day and night (atenolol, valsartan) and others displayed both behaviours – with a higher elimination during day time (bisoprolol, DEET or TAED). Part of the compounds list was investigated in a previous experiment also performed in the Steinlach but at only two control planes in July 2013. Similar behaviour were found with however a better attenuation in the last experiment. Finally, unlike 2013 sampling, 2015 experiment could supply decay profiles, particularly interesting for compounds like DEET.

3
Abiotic and biotic fate of lamotrigine N2-glucuronide in wastewaters and surface waters
B. Zonja, S. Perez, IDAEA-CSIC / Environmental Chemistry; D. Barcelo, IIQAB-CSIC / Dept Environmental Chemistry
Lamotrigine, an anticonvulsant, is a xenobiotic which is extensively and predominantly transformed by phase II metabolism to its N2-glucuronide before it is excreted from the human body. Both parent and metabolite have been detected in the wastewater system, surface and groundwater. In this work, we tested a suspect-screening approach in order to detect lamotrigine and its related compounds like other human metabolites, impurities and phototransformation products in the aquatic system. Environmental samples that were preconcentrated using generic solid-phase extraction and analysed by liquid chromatography - high resolution mass spectrometry method suggested lamotrigine undergoes unusual transformations. However, biodegradation reactors amended with mixed liquor at neutral pH showed that lamotrigine is resistant to biodegradation with only about 5 % elimination after 6 days. When its human metabolite (N2-glucuronide) was degraded following the same experimental setup, it was discovered that the metabolite is in fact the source of the transformation products (TPs) detected. In batch experiments, N2-glucuronide was transformed to three TPs as a result of i) deconjugation, ii) oxidation of the glucuronic acid and iii) amidine hydrolysis in combination with deconjugation. All these compounds were detected in wastewater treatment plant (WWTP) influent and effluent, and surface water samples analysed. Additionally, in the WWTPs, these TPs helped explain the mass balance of the N2-glucuronide. Apart from the biotic reactions, the abiotic stability of the glucuronide in the pH range 4 - 9 was tested in order to characterise the possible formation of amidine and guanidine hydrolysis TPs. This was performed in various environmental matrices. Other N2-supsituted lamotrigine derivatives were tested as well in order to test the influence of N2-supsitution on reaction kinetics. Results showed that N2-glucuronide was transforming via amidine (primarily) and guanidine hydrolysis under neutral-basic pH and the transformation rate was exponentially increased with the increase of pH. Moreover, this reaction was shown to depend on imine tautomer equilibrium and imine tautomer formation depended directly on the N2-supsitutent. In the end, the presented work intents to give a new insight into the behaviour of glucuronides of pharmaceuticals, and suggest that they can also be sources of environmentally relevant but yet undiscovered TPs.

4
Micropollutans - how to cope with the residues?
A. Zenker, University of Appl. Sc. Northwestern Switzerland / Institute of Ecopreneurship; T. Wintgens, University of Applied Sciences Northwestern Switzerland (FHNW), School of Life Sciences, Institute of Ecopreneurship; J. Loewenberg, CSD Ingenieure AG; J. Svojitka, R. Hochstrat, University of Applied Sciences Northwestern Switzerland (FHNW), School of Life Sciences, Institute of Ecopreneurship; S. Schmidt, University of Applied Sciences Rapperswil, Institute of Environmental and Process Engineering; M. Burkhardt, UMTEC, HSR Hochschule für Technik Rapperswil
Most recently Switzerland as one of first countries worldwide has changed its Water Protection Ordinance demanding about 100 wastewater treatment plants (WWTP) to upgrade with an additional treatment step. The additional step should help reducing 80% of micropollutants' load of the influent over the whole sewage treatment process. Micropollutants are present at low concentrations in aquatic environment ranging from ng/L - μg/L, but their negative effects on biota have already been demonstrated. Ozonation and the adsorption of micropollutants by powdered activated carbon (PAC) are currently the most promising techniques to eliminate micropollutants in WWTPs. An overview of different techniques to eliminate micropollutants in waste water, stormwater and drinking water will be presented. Different adsorber materials like PAC (SAE Super, Sorbopor MV 125, Carbopal AP, Pulsorb WP 260), granular activated carbon (GAC) and resin based adsorbers were tested in combination with flotation, deep bed filtration and

ultrafiltration to reduce micropollutants. These settings were tested under laboratory conditions, in pilot scale and subsequently upscaled in the treatment plants themselves. To monitor the removal lead substances from 48h composite samples including pharmaceuticals such as carbamazepine, diclofenac, sulfamethoxazole, the herbicide mecoprop and the corrosion inhibitor benzotriazole were determined. Measurements were carried out on a high performance liquid chromatography coupled to triple quadrupole mass spectrometer. It was shown that the combination of PAC and filtration or PAC and flotation are suitable technologies to remove nearly 80% of the micropollutants' load of urban and industrial wastewater. During the operation duration of several months the removal was robust and less prone to faults.

5
Do pharmaceuticals bioaccumulate in marine molluscs and fishes from a coastal lagoon?
V. León, R. Moreno-González, Instituto Español de Oceanografia / Centro Oceanográfico de Murcia; S. Rodriguez-Mozaz, Institute for Water Research (ICRA) / Water Quality; B. Huerta Buitrago, Catalan Institute for Water Research (ICRA) / Institute of Environment Health and Societies; D. Barceló, IDAEA-CSIC / Department of Environmental Chemistry
The pressure and impact of organic pollutants are greater in coastal areas than in the rest of the marine environment, since these are where many human activities are concentrated and direct and indirect discharges occur. In the marine environment, pharmaceuticals have predominantly been found in seawater, but less so in sediment. However, field data of the bioaccumulation of pharmaceuticals in marine organisms exposed to environmental conditions is rather sparse and concentrations of pharmaceuticals in marine fish have only been determined in a small number of areas. The aims of this study were to determine the concentration of pharmaceuticals in cockle, noble pen shell, sea snail, golden grey mullet and black goby in spring and autumn; and to assess the bioaccumulation in cages clams in 4 sites with different exposition grade to El Albujón watercourse dischargue. A method proposed for the determination of 20 multi-class pharmaceuticals in fish tissues (was adapted for grey golden mullet muscle and liver and for the following molluscs: clam, noble pen shell, and sea snail. Eighteen out of the 20 compounds analyzed were found at low ng g^{-1} in these species throughout the lagoon. Hydrochlorothiazide and carbamazepine were detected in all species considered. The bioaccumulation of pharmaceuticals was heterogeneous in the lagoon, with a higher number of pharmaceuticals being detected in fish (19) than in wild molluscs (10), particularly in golden grey mullet muscle (16). The bioaccumulation of pharmaceuticals was lower in sea snail than in bivalves, and in black goby than in golden grey mullet. Psychiatric drugs preferentially bioaccumulated in fish muscle, while citalopram did so in molluscs. Carbamazepine and hydrochlorothiazide were detected in all species in this study. The higher detection frequency and concentrations found in golden grey mullet (muscle) suggested that mugilids could be used as an indicator of contamination by pharmaceuticals in coastal areas. *Acknowledgement* - This work was supported by the Seneca Foundation (Region of Murcia, Spain) through the 'BIOMARO' project (15398/PI/10), the Spanish Inter-Ministerial Science and Technology Commission through the 'IMPACTA' project (CICYT, CTM2013-48194-C3-1-R) and by the European Union through the European Regional Development Fund (ERDF). It was also partly supported by the Generalitat de Catalunya (Consolidated Research Group: Catalan Institute for Water Research 2014 SGR 291).

6
Impacts of compound properties and sediment characteristics on the sorption behavior of pharmaceuticals in aquatic systems
O. Abdullah, University of York / Environment; A. Boxall, University of York / Environment Department
Sorption is akey factorin determining the persistence and attenuation of pharmaceuticals in sediment and will therefore affect the impact that a pharmaceutical has on aquatic organisms. However, our understanding of the relationships between sediment characteristics and pharmaceutical sorption behavior is lacking as most studies into the sorption behaviour of pharmaceuticals focus on their behaviour in sewage sludge and soil.In this study, the sorption behaviour of five different pharmaceuticals in ten sediments from the UK and Iraq, with different properties, was assessed. Batch sorption studies with the pharmaceuticals were performed and the sorption affinity for all sediments was found to increase in the ordermefenamic acid < cimetidine < atenolol < amitriptyline < diltiazem.An existing predictive model for estimating the sorption of ionisable compounds was evaluatedagainst the experimental data. The model tended to over-predict the sorption of the basic compounds and under-predict the sorption of the acidic compounds. Multiple linear regression analysiswas therefore used to development new models for estimating the sorption (Kd) of the study pharmaceuticals from sediment properties. Sediment and pharmaceutical parameters used in the models were: (a) log Dow (lipophilicity corrected for pH) for amitriptyline, (b) cation exchange capacity for atenolol, (c) clay and organic carbon content for cimetidine,(d) log Dow and exchangeable Ca^{2+} for diltiazem and (e) organic carbon contentfor mefenamic acid. The validity of the proposed regression equations was tested using independent data and gave good results for atenolol. Overall, the results demonstrate how complex the processes driving the sorption of pharmaceuticals in sediments are and the need for generation of further experimental dataand additional model development for estimating sorption of pharmaceuticals.

Microplastics in the environment: Sources, Fate and Effects (I)

7
Micro- and mesoplastic in Atlantic cod (Gadus morhua) from the Norwegian coast
d.p. eidsvoll, Norwegian Institute for Water Research (NIVA); I. Nerland, NIVA Norwegian Institute for Water Research / Ecotoxicology and Risk Assessment; C.C. Steindal, University of Oslo / Museum of Cultural History; K.V. Thomas, NIVA Norwegian Institute for Water Research / Product Metabolism
Microplastics contaminate oceans and affect marine organisms in several ways. This study documents microplastic (< 5mm) and mesoplastics (>5mm) in stomachs from cod (Gadus morhua) one of the most common and economically important marine fish in Norway. 302 fish stomachs were examined from six different locations from the coast of Norway. Ten individual stomachs had items in them identified as synthetic polymers, eight of these were from one location (Bergen). All objects found in the stomachs were Fourier Transform Infrared Spectroscopy (FTIR) scanned and subsequently compared with FTIR libraries to confirm identity of the removed items. In this study all stomachs where plastics were found, were full. Empty stomachs had no presence of plastic.\nThis study provides a record of plastic polymers being identified in the stomachs of cod in three out of six locations. We found the presence of polyethylene terephtalate (PET or PETE) and polyester, polyvinyl chloride (PVC), polypropylene (PP), polystyrene (PS), acrylic and nylon (Other). We identified a hot spot for plastic ingestion in Bergen. Our findings indicate that plastic pieces are more prevalent inside fish with a full stomach content versus those with empty stomachs. Therefore, pieces large enough to be visually identified through a stereo microscope may be flushed out of the stomach region of the GI tract. Further work is needed to establish the sources and potential consequences of microplastics.

8
Fragmentation of plastic items into secondary microplastics under environmental conditions
J. Klasmeier, University of Osnabrueck / Institute of Environmental Systems Research; A. Reuwer, Osnabrück University / Institute of Environmental Systems Research
Marine plastic debris of all size classes contaminates marine waters and coastlines worldwide. Larger plastic items are suspected to be fragmented under external friction exerted by water currents, rocks or sediments. Weathering, abrasion or disruption of plastics may result in an increasing number of secondary plastic debris. Main goal of this research was the systematic investigation of the fragmentation behavior of plastic material under conditions typically experienced in the marine environment. PE bottles (1 L) were filled with 1 kg pre-cleaned sand (beach conditions), and half of the samples were additionally spiked with 300 mL artificial seawater (breakwater conditions). Plastic items of different polymer material (PE, PP, PS, PET) and form (cups, small bottles, bottle caps, thin foils, film strips) were addd and shaken for 30 days in an overhead shaker. After 30 days, intact items and larger plastic fragments were sorted out by hand. Samples were extracted for microplastic particles using a simplified adaptation of a flotation method developed in our lab. Extracted particles were visually inspected under a microscope and sorted into different size classes. Some randomly selected particles from each size class were analyzed with FTIR (Bruker Vertex 70) to identify the polymer material. All investigated items bear visible traces of mechanical abrasion. Film strips and bottle caps did not fragment, but abrasion of material from the surface had obviously occurred. Thin foil sheets were partly perforated and fragmented into a number of mesoplastic and large microplastic particles of elongated shape. The other investigated items were fragmented into more or less smaller particles after 30 days. Microscopic size analysis of the PS cup sample resulted in four mesoplastic fragments, 35 large microplastic particles (1 – 5 mm) and 32 small microplastics (

9
Analysis of microplastic in environmental samples using thermal analytical methodes
U. Braun, E. Duemichen, A. Barthel, BAM- Federal Institute Materials Research and Testing; N. Becker, C. Bannick, UBA Umweltbundesamt
The increasing amount of polymers in practical use with their excellent material properties, such as low weight, easy processing and high stability against various chemical attacks, will also increase the unfavoured presence of plastics in the environment. These plastics and small-degraded plastic particles, called microplastic, are almost ubiquitary in nature. Up to now, no verified data exist about the source, the fate and the amount of various plastics in water, soil, air and biota. The reason for this is that no fast and easy available method exists, which detect the small amount of synthetic polymers beside a large amount of natural

macromolecules in various environmental matrices. Known, microscopic-spectroscopic methods are limited due to very large measurement times, high sophisticated evaluation knowledge or method specific limitations such as sample preparation in infrared analysis or fluorescence of environmental matrix in Raman. Furthermore, no quantitative value can be determined by these methods. Quantitative values, which include the whole range of synthetic polymers, are a prerequisite for administrative regulations. A practicable alternative is the thermal extraction desorption- gas chromatography-mass spectroscopy (TED-GC-MS) [1]. In this method, the advantages of TGA (high samples loadings and an easy cleaning) are combined with the advantages of GC-MS (easy identification of various hydrocarbon products with high certainty). In TGA, a large amount of sample is decomposed. The formed volatile decomposition products can be trapped on the surface of an adsorber material located at the outlet of TGA and collects a representative content of hydrocarbon decomposition. The decomposition products are analysed in a common TDS-GC-MS. The comfortable identification of characteristic decomposition products enables the fast identification of various polymers. Beside the investigation of various spiced environmental samples for the presentation of this new method, we present data of real environmental samples. These are air and water filtrates from various sources as well as samples from composting plants and streets. Samples are measured as received or after treatment with chemical solutions. [1] E. Dümichen, A.-K. Barthel, U. Braun, C. G. Bannick, K. Brand, M. Jekel and R. Senz, *Water Research* **2015**, *85*, 451-457.

10

Role of microplastic beads on the uptake of silver in zebrafish

F. Khan, Roskilde University / ENSPAC; D. Boyle, University of Plymouth / School of Biomedical and Biological Sciences; E. Chang, Kings College London; K. Syberg, Roskilde University / Department of Environmental Social and Spatial Change; Y. Shashoua, The National Museum of Denmark; N. Bury, Kings College London / Division of Diabetes and Nutritional Sciences

This study aimed to determine whether the uptake and localization of Ag in zebrafish was affected by the presence of polyethylene microplastic beads (PE MPBs). Zebrafish were exposed to 1 μg Ag L^{-1} (radiolabelled with ^{110m}Ag) for 4 and 24 h in the presence or absence of PE MPBs (10, 100 or 1000 MPBs mL^{-1}), and one treatment in which MPBs (1000 MPBs mL^{-1}) were incubated with Ag to promote adsorption. The presence of MPBs, at any of the tested doses, had no effect on the uptake or localization of Ag. However, exposure to the Ag-incubated MPBs (?75% of the Ag bound to MPBs) significantly reduced Ag uptake at both time points and also significantly increased the proportion of intestinal Ag. This study demonstrates that microplastics can alter the bioavailability and uptake route of a metal contaminant in a model fish species. A second study was undertaken to investigate the fate of Ag transported into the gut along MPBs. THis sencond study utilised in vitro gut sac preparations, but showed minimal differences in the internal fate of Ag regardless of its interation with the MPBs,

11

Comparison of tissue preparation procedures to perform microplastic analysis; application to mussels (Mytilus edulis) from the Atlantic coast (Pays de la Loire, France)

N.N. Phuong, Nantes University; A. Zalouk-Vergnoux, L. Poirier, Univeristé de Nantes / MMS; A. Kamari, Universite de Nantes / MMS; J. Rouxel, R. Sussarellu, F. Akcha, IFREMER; A. Chatel, Université Catholique de lOuest / Sciences Environnement; C. Mouneyrac, Université Catholique de lOuest / UNAM Université Nantes Angers Le Mans Mer Molécules Santé MMS; f. lagarde, Institute of molecules and materials of Le Mans / Institute of Materials and Molecules of Le Mans IMMM UMR CNRS

Plastics is a generic name to encompass most of the synthetic organic polymers exhibiting the property of plasticity. These products are characterized by many advantages which explain that they are massively used in our everyday life. Since the middle of the last century, several million tons of plastics have been produced. Ten percent of produced plastics is estimated to end up in the ocean. Once in the environment, macro debris undergo mechanical (erosion, abrasion), chemical (photo-oxidation, temperature, corrosion) and biological (degradation by microorganisms) actions. All these degradation processes lead to their fragmentation into microplastics (MPs) which accumulate in the environment. According to the last ten years of research, it appears that all natural habitats from pole to pole are affected by the presence of MPs. In these research works, many different procedures were used for MP quantification and characterization in environmental samples. Consequently, the aim of this study was to compare different tissue preparation procedures found in the literature to select the more appropriated. For that, counted MPs of two different forms (fragments and fibers) and types (PE and PVC) were added to three mussels (*Mytilus edulis*) for a digestion step implementing different solvents or mix of solvents. Then, the filtration step was performed using different types of filters. The efficiency of the digestion step was calculated from the masses of the filters related to the initial mussel masses and the preservation of the MP integrity was evaluated by using microscopy coupled to Raman and Infra-Red micro-spectrometers. The ratios were lower with the use of HNO_3 (65%) for the digestion. Nevertheless, the MP integrity was not preserved for all types of MPs added to the mussels since PE fibers were totally dissolved despite good recoveries for PVC and PE fragments. The determination of the better sample preparation procedure is quite difficult since it involves a compromise between efficient digestion of organic matter from mussel tissues and the preservation of the integrity of MPs. HNO_3 was however selected for the following analyzes since the lower organic matter amounts enhanced better microscopic and spectroscopic analysis. Finally this procedure was applied for the evaluation of MP contamination of mussels (*M. edulis*) from the Atlantic coast (Pays de la Loire, France).

Pollution of the oceans by microplastics, defined as plastic particles of size below < 5mm by the NOAA, represent a major environmental problem worldwide. From an ecotoxicological point of view, the ingestion of microplastics by a wide range of marine organisms leading to substantial impacts on major physiological functions has been shown in several marine vertebrates and invertebrates. To date, only a few studies have investigated the levels of contamination of marine organisms collected *in situ*, partly due to technical difficulties in isolation and characterization of microplastics in biological samples. The crucial step is the identification of solvent(s) or chemical(s) that efficiently dissolve organic matter and biological tissues without degrading plastic polymers, and this in a time and cost effective way. Most published papers, as well as OSPAR recommendations for the development of a common monitoring protocol for plastic particles in fish and shellfish at the European level,used protocols containing nitric acid to digest the biological tissues, despite reports of substantial degradation of some polyamide types (also known as nylon) with this solvent. In addition, testing a wide range of plastic polymers, and especially those commonly found in the marine environment is essential to validate a common protocol and avoid an underestimation of plastic contents in marine organisms after tissue digestion. In the present study, we reviewed existing approaches and we compared (i) their efficiency in digesting biological matrixes and (ii) their effects on 5 different plastic polymers. Effects on plastics were evaluated through visual inspection, weighing and Raman analyses before and after digestion, while tissue digestates were filtered on 1μm-mesh fiber glass filters and observed using a binocular microscope. More research is currently ongoing in our laboratory on a wider range of plastic types (n=15 in total). The aim is to identify and validate a unique and standardized protocol that could be implemented at the international level to insure relevance and comparison of environmental studies on this topic.

Behavior Revised: Examining Behavioral Effects of Contaminants and Other Stressors in Aquatic Animals

Why are avian focal species unaffected by chlorpyrifos applications? Integrating data on foraging-behaviour, exposure, and toxicokinetics

M. Foudoulakis, Dow Agrosciences / RSRA ERS; S. Norman, RidgewayEco; C. Wolf, B. Giessing, Tier3 Solutions GmbH; R. Dittrich, Tier3 Solutions GmbH / Wildlife Ecology; N.N. Poletika, Dow Agro Sciences LLC / Field Exposure and Effects Department; G. Weyman, ADAMA Agricultural Solutions Ltd.

Tier 1 avian risk assessment indicates high risk from use of chlorpyrifos (CP) due to its high toxicity to birds when tested in standard laboratory studies. However, when aiming to conduct a proper risk assessment, it is important to understand the status and ecology of the bird community present in the target crop at field level. In this respect, it is important to estimate basic population parameters of species breeding within the treated fields (long term survival and reproductive performance), their foraging behaviour and feeding ecology, and the spatial & temporal movement of the focal species to evaluate the factors (both natural and anthropogenic) which may influence reproductive performance and community of birds present. In addition it is equally important to collect exposure and mechanistic data to support and explain findings in the field. Several field studies have been conducted towards this aim. To gain information on the bird communities within the CP-treated fields a variety methods were used depending on the goal of the study and the species in focus, which allows measurement and ranking of any factors influencing the local bird community, including the application of CP itself. The work undertaken over consecutive years gave a good insight into exposure of birds utilizing treated fields/fruit orchards and showed a good correlation between the application of CP and cholinesterase (ChE) activity in the same bird communities, providing a diagnostic evaluation of CP exposure.

In order to support field findings and provide a higher tier risk assessment on birds, mechanistic information were also provided based on body burden model describing Toxicokinetics and Toxicodynamics. This presentation will describe the comprehensive and holistic approach which was followed, the new approaches for bird studies in risk assessment over consecutive years of data collection and will answer why the high risk of mortality predicted by the Tier 1 risk assessment is not seen in the field.

14

Sex and steroids: Impact of a pervasive endocrine disrupting agricultural pollutant on sexual selection in fish

M.G. Bertram, Monash University / Biological Sciences; M. Saaristo, T.E. Ecker, B.B. Wong, Monash University / School of Biological Sciences

Environmental contamination with endocrine disrupting chemicals (EDCs) threatens human and wildlife populations globally. The sub-lethal effects of endocrine disruptors at environmentally realistic levels are receiving increasing attention, including the impacts of exposure on behaviours influencing survival and reproductive fitness. Despite this, understanding of how these biologically active pollutants impact processes of sexual selection is rudimentary. In the present study, we investigated the effects of EDC-exposure on male mate choice, a key component of sexual selection and a driver of evolution by natural selection. Specifically, the aim of this study was to examine the impacts of short-term (21-day) exposure to an environmentally relevant concentration of 17b-trenbolone (measured concentration 6 ng/L)—an androgenic growth promoter used in the cattle industry globally that has been repeatedly detected in freshwater systems—on mate choice in the guppy (*Poecilia reticulata*). The guppy is a sexually dimorphic livebearer, with males inseminating females using their modified anal fin (the gonopodium) as an intromittent organ. Male guppies are choosy and prefer larger females as mates, and therefore gain fitness benefits as female guppy fecundity (brood size) increases with body size. Given that male mate choice is a key component of sexual selection, regarding not only whether to mate, but also the allocation of reproductive investment between each mate or mating, this male choosiness is key to reproductive fitness. To test the effect of exposure to 17b-trenbolone on male guppy preference for female size, we used a free-swimming experimental design, within which a pair of male and female guppies were tested in one of four treatments as follows: (1) unexposed male with 'large' stimulus female, (2) exposed male with 'large' stimulus female, (3) unexposed male with 'small' stimulus female, and (4) exposed male with 'small' stimulus female. We measured the time and frequency of male courting behaviours, as well as male structural colouration and morphology. The results of the mating behaviour trials, as well as colouration and morphological analyses, will be discussed with reference to the broader ecological and evolutionary consequences of EDC exposure.

15

Effects of the NSAID Diclofenac on the survival, health and behaviour of embryonic and juvenile brown trout Salmo trutta f. fario

S. Schwarz, University of Tuebingen / Animal Physological Ecology; H. Schmieg, Tübingen University / Animal Physiological Ecology; M. Scheurer, Water Technology Center TZW Karlsruhe; H.-. Köhler, University of Tuebingen / Institute of Evolution and Ecology Animal Physiological Ecology; R. Triebskorn, University of Tuebingen / Animal Physiological Ecology

While the presence of various pharmaceuticals of anthropogenic orgin in surface waters has frequently been shown, the ecological impact of the detected substances is still hardly assessable. Within the project "Eff-Pharm", new mode-of-action based *in vitro* systems for the monitoring of non-steroid anti-inflammatory drugs are developed. Simultaneous *in vivo* studies on diclofenac, a common and widely used representative of this pharmaceutical group, provide further information on possible effect concentrations. The brown trout has been investigated as a species of high local environmental relevance for Central European stream ecosystems. Our aim was to investigate two supposedly sensitive stages of trout life history: the embryonic development from fertilized egg until the end of the sac-fry stage, and juvenile fish around 6 months post hatch. The exposure of trout embryos and sac-fry stages was conducted according to OECD guideline 212, and included five test concentrations (0.1, 0.5, 1, 10 and 100 μg/L diclofenac) plus control - tested in triplicates for 127 days at 7 °C. Recorded endpoints were mortality, time until eye development, time to hatch, number of hatched larvae, heartbeat and histological condition of the fry. Juvenile trout (approx. 6 months post hatch) were exposed in a semi-static three-block design (control, 0.1, 1, 10, 100 and 200 μg/L diclofenac per block) for 25 days at 7 °C. Besides examining mortality, biometric parameters and behavioural abnormalities, additional biochemical analyses determined stress protein level. In addition, lipid peroxidation was measured and histological examinations were conducted in liver, gill and kidney tissues. None of the investigated parameters was altered in the embryos and fry. In contrast, juvenile fish showed increased mortality already at 0.1 μg/L diclofenac. Mortality rate was concentration dependent and reached up to 43 % in the highest test concentrations, while it did not exceed 10 % in the control. Furthermore, fish exposed to 10 μg/L diclofenac or higher showed a higher frequency of bite marks, a sign of increased territorial behaviour. Further histological analyses will give us a closer insight into the health state of the surviving individuals. Overall, the study showed alarming results on the toxicity of a commonly used NSAID. It also stresses out the importance of investigating different life stages to fully assess the potential effect of chemicals in the aquatic environment.

16

Can zebrafish larvae behaviour be used for on-line contamination event detection in water distribution systems?

L. Nuesser, RWTH Aachen University, Institute for Environmental Research / Department of Ecosystem Analysis; E. Salomons, Technion Israel Institute of Technology; O. Skulovich, Technion Israel Institute of Technology / Civil and Environmental Engineering; S. Hartmann, RWTH Aachen University / Institute for Environmental Research; C. Ganal, C. Cofalla, H. Schuettrumpf, RWTH Aachen University / Institute of Hydraulic Engineering and Water Resources Management; A. Ostfeld, Technion Israel Institute of Technology; H. Hollert, RWTH Aachen University / Department of Ecosystem Analysis; T. Seiler, RWTH Aachen University / Ecosystem Analysis

Changes in motoric behaviour of organisms as a response to the exposure to chemicals are a sensitive endpoint for the assessment of toxicity [1]. Monitoring of zebrafish (embryo, larvae and adult) behaviour emerges as new, sensitive method to study effects of compounds in a vertebrate model. Here, we propose to use behavioural changes of zebrafish larvae for the detection of sudden contamination events in a water stream. Zebrafish larvae at the age of 96 hours post fertilization (hpf) were exposed to cadmium chloride (CdCl2) in a low concentration range and immediately monitored for avoidance behaviour which results in an increased activity. Here we propose two methods for the analysis of behaviour data and sensitive detection of alterations that have the potential to be for on-line data streams. For the first approach data on the distance larvae moved was pooled within groups (control n=16; 4 treatment groups at different concentrations with n=20 each) and averaged for one minute per group. In this approach two upper thresholds for maximal activity of the larvae during darkness were defined (180 mm/min and 200 mm/min). For the second approach the x- and y-coordinates of the larvae's movement where transformed to polar coordinates in order to calculate the angle of their movement. Thresholds for the angle allow distinguishing between undirected movement of the larvae and directed circular swimming behaviour that can be regarded as avoidance behaviour. First results show that the proposed approaches are suitable methods to detect alterations in zebrafish larvae behaviour in response to low concentrations of CdCl2. The thresholds presented in this study are sensitive with a minimum in false positive alerts and have the potential to be used for the analysis of an on-line data stream. The second approach considers the directed behaviour of the larvae and therefor allows for the detection of a distinct parameter that appears to be a sensitive indicator during the light cycles.

The mechanism of oil sands process-affected water on feeding-behaviour toxicity in Daphnia magna

E. Lari, D. Steinkey, E. Mohaddes, G.G. Pyle, University of Lethbridge / Biological Sciences

Oil sands process-affected water (OSPW) is produced as a byproduct of the surface-mining oil sands industry in northeastern Alberta. Responsible remediation and returning OSPW to natural environment is a big concern of both oil-sand companies and scientists. Such a return would need to minimize the impact to downstream ecosystems. In our previous studies we showed that OSPW decreases the feeding activity of *Daphnia magna*. To understand the mechanism of OSPW's effect on feeding behavior we exposed *D. magna* to three substances [filtered OSPW (chemical portion), filtered OSPW plus added clay particles (whole OSPW), and clay particles suspended in solution (particulate portion)] and we used *Daphnia magna* culture water as an exposure control. We fed the animals similar quantities of their food algae, and gave them 24 h (in darkness) to graze. After 24 h we measured the food consumption in all treatments and the exposed *D. magna* were used for further experiments to understand the mechanism of effect of the components of OSPW on feeding activity of *D. magna*. For the behavioural bioassay, using a behaviour chamber designed for this study we examined the thoracic limbs and mandible beating as indicators of feeding rate of *D. magna*. We measured the activity of twodigestive enzymes (amylase and trypsin) as representatives of digestion of *D. magna*. Our results fromall studied biological levels showed whole OSPW significantly affects thoracic limbs and mandible movement, gut clearance, and digestive enzyme activity of *D. magna*. Particulate matter component of OSPW is most effective and chemical components are less effective in the observed reduction in the feeding behaviour of *D. magna*.

Comparative behavioral toxicology of two common fish models

B. Steele, Baylor University / Biomedical Studies; L.A. Kristofco; J. Corrales, Baylor University / Environmental Science; B.W. Brooks, Baylor University / Environmental Health Science Program Department of Environmental Science

Behavioral responses inform toxicology studies by rapidly and sensitively detecting molecular initiation events (MIEs) that propagate to physiological changes in individuals. Behavioral thresholds for a wide range of contaminants often manifest at lower levels than those eliciting mortality and other standardized adverse outcomes. Zebrafish larvae are common models in behavior, developmental toxicology, neurotoxicology and other biomedical studies. Whereas the fathead minnow is a common model for aquatic toxicology research and regulatory programs, they have received comparatively little attention in behavioral studies. We employed the zebrafish and fathead minnow models to define toxicant induced swimming activity alterations during interchanging photoperiods. We specifically examined behavioral response patterns among compounds specifically targeting various receptors/enzymes compared to response profiles for chemicals eliciting toxicity through narcosis. Following OECD FET and EPA WET experimental guidelines, zebrafish embryos and fathead minnow larvae were exposed for 96 h to each compound, then observed using a digital behavioral analysis system (ViewPoint). Behavioral observations occurred for 50 minutes (10 minutes acclimation, two 10 minute dark periods, two 10 minute light periods). In comparison to fathead minnow larvae, zebrafish generally displayed greater behavioral sensitivities to a number of the investigated compounds. Furthermore, zebrafish displayed more pronounced responses to changing light and dark photoperiods than the fathead minnow model. Such photomotor response profiles for compounds with defined MIEs are being used to examine industrial chemicals for which behavioral responses are poorly understood.

Fate, Effects and Risk Assessment of Chemicals in Aquatic and Terrestrial plants (I)

Spatial and temporal distribution of pesticides and their metabolites in tomato plants

M. Kubicki, TU Dortmund / Institute of Environmental Research; M. Lamshoeft, Bayer CropScience AG / RD; S. Zühlke, M. Spiteller, TU Dortmund / Institute of Environmental Research

Knowledge about translocation of plant protection products (PPP's) in plants is important to understand the uptake via the root system. Imaging mass spectrometry (IMS) has been widely used in life science and has proven to be a powerful tool to combine histological data with specific molecular information. So far phospholipids, peptides, drugs and plant metabolites were imaged in a number of tissue samples at a spatial resolution of 5–10 μm[1-4]. The IMS data for all these experiments showed excellent correlation with histological staining evaluation. Thus, IMS allows exploration of both PPP's and their metabolites distribution in plant tissues and provides new knowledge concerning behaviour during plant growth. Within a single experiment two-dimensional spatial maps of parent compound and metabolites can be generated. We report here the use of a matrix-assisted laser desorption/ionization (MALDI) imaging source working at atmospheric pressure which is coupled to an orbital trapping mass spectrometer for new insights into molecular processes inside the plants. Therefore, spray application onto the tissue using selected matrix solution has to be optimised, supporting desorption and ionization of target compounds by means of a focused laser. This sample preparation is important to improve sensitivity and spatial resolution of the IMS-measurement and finally to generate the images. Here, we report the use of MALDI-high resolution-IMS to map the distribution of two selected PPP's (the phenylamide fungicide metalaxyl and the triazole fungicide tebuconazole) and their metabolites in roots, stem and leaves of tomato plants in high-spatial resolution with minimised sample preparation. The combination of autoradiography of ^{14}C-labelled compounds, LC-HRMS^n, and MALDI-IMS provides comprehensive information of distribution, localization and dynamics of PPP's uptake via the root system of tomato plants.

20

Toxicity testing with the willow tree transpiration test - 15 years of results

S. Trapp, Technical University of Denmark / DTU Environment; L.P. Clausen, Technical University of Denmark / Department of Evironmental Engineering

Due to the large size of trees, their slow growth and the related difficulties, few toxicity tests for trees have been developed, and no standard test is available. A toxicity test using the transpiration of willows is in use since 15 years [1]. The willow tree toxicity test was employed for toxicity testing, for phytoremediation purposes and for process studies in the soil-plant system. Genetically homogenous willow cuttings are grown under artificial light in 500 mL Erlenmeyer flasks filled with spiked nutrient solution (ISO 8962), contaminated soils, wastewater or other test substrate [1]. The toxic endpoint is the change of transpiration, which is measured daily by weighing the whole flask, compared to the transpiration of control trees. **\n** EC50-values of more than 50 compounds obtained under various conditions. EC50-values < 1 mg/L were obtained for Cu(2+). Cd(2+), As (arsenate) and Se have EC50 close to 1 mg/L. Among the pharmaceuticals tested, the most toxic was the weak acid ibuprofen with an EC50-value of 1.7 mg/L, but only at pH 4, and much less toxic at higher pH. Diclofenac (100 mg/L) and paracetamol (3000 mg/L) were less toxic in this test. The bivalent base chloroquine had an EC50 of 2.5, 10, 35, 40 mg/L at pH 9, 8, 7, 6, respectively [2]. The toxicity of chlorophenols declined from 1.1 mg/L (3,5-DCP) to 5.8-10 mg/L (2,4-DCP) to 32-84 (4-chlorophenol) and 400 to 800 mg/L (phenol). The toxicity of cyanide depended very much on the complexation, from rather non-toxic 1000 mg/L Prussian blue (ferriferrocyanide, FeII,FeIII-complex) to quite toxic with EC50 at 2 mg for KCN. Toxicity to willows grown in sand was generally lower, for example, EC50 was 20 mg/L for KCN in sand. Little toxicity (contrary, growth stimulation at lower dosage) was observed for nano-TiO2 (> 100 mg/L) and zero-valent iron nanoparticles (around 1000 mg/L) in solution. A user manual has been developed and is freely available (http://homepage.env.dtu.dk/stt/). Overall, the willow tree test is probably the most widely used toxicity test with trees and could be seen as a candidate for a standard toxicity test for woody terrestrial plants. [1] Trapp S, Zambrano KC, Kusk KO, Karlson U. 2000. A phytotoxicity test using transpiration of willows. Arch. Environ. Contam. Toxicol. 39(2):154-160

Uptake of pharmaceuticals from wastewater into plants - Novel carbamazepine metabolites in tomato plants grown under hydroponic conditions

C. Riemenschneider, Helmholtz centre for environmental research - UFZ / Analytical Chemistry; B. Seiwert, Helmholtz centre for environmental research - UFZ / Department of Analytical Chemistry; D. Schwarz, Leibniz Institute of Vegetable and Ornamental Crops - IGZ; M. Moeder, Helmholtz centre for environmental research - UFZ; T. Reemtsma, Helmholtz Centre for Environmental Research

Water scarcity is one of the main challenges in arid and semiarid regions. Therefore, the use of treated wastewater (TWW) for crop irrigation is a necessity. Under these circumstances pollutants of emerging, with low removal efficiency in wastewater treatment plants, are introduced into the agro-ecosystem and may be transferred from irrigation water into edible plants and thus enter the food chain [1-3]. However, until now little work has been done to investigate the metabolism of PPCPs after uptake into plants. We studied the uptake and metabolism of PPCP from wastewater into plants with carbamazepine (CBZ) as model compound, an antiepileptic drug which is a commonly detected pharmaceutical in wastewater, surface water and even groundwater [4]. Tomato plants grown in hydroponic cultures were analyzed with both targeted analytical methods (LC-MS/MS) that offer higher sensitivity and liquid chromatography-high resolution mass spectrometry (UPLC-Q-TOF-MS) to identify unknown metabolites. A total of 10 phase-I and three phase–II metabolites could be detected from the one contaminant CBZ. Considering these known CBZ metabolites the overall concentration was about 1.5-fold (for tomato leaves and fruits) higher than that of CBZ alone. This example illustrates that, due to plant metabolism, the concentration of contaminants found in plants can be significantly higher than the concentration of the parent compound. However, further study is needed to evaluate the potential toxicological effects of these metabolites and the consequences for the safe reuse of treated wastewater in agriculture. In addition, further research is required to better understand and possibly to predict the metabolism of compounds within plants in terms of potential consequences for modelling. Aquatic macrophyte modelling - Increasing the realism of risk assessments

S. Heine, Bayer CropScience / Environmental Modelling; K. Kuhl, A. Solga, Bayer CropScience AG; E. Bruns, Bayer CropScience AG / BCS D ETX Ecotoxicology; T. Preuss, Bayer CropScience / Environmental Modelling; G. Goerlitz, Bayer CropScience AG / Environmental Safety

For the registration of plant protection products, the risk on aquatic macrophytes has to be assessed. This is done by predicting the annual concentration pattern of a plant protection product in several surface water systems considering its specific agricultural application. To assess the risk on aquatic macrophytes, as a first step, the maximum concentration that is predicted throughout the year is compared to toxicity endpoints, such as EC50 values. In most cases, these toxicity endpoints are based on studies considering constant concentrations of the respective plant protection product. A method to increase the realism (higher tier) of the risk assessment is to use toxicity studies that are based on exposure patterns similar to those predicted in surface water systems. To date, this approach is mostly applied to short term exposure patterns, having a duration of less than a week, due to the time range of standard macrophyte toxicity studies. This contribution demonstrates ecological modelling methods, in terms of toxicokinetic and toxicodynamic (TK/TD) growth models of *Lemna* spp. and *Myriophyllum spicatum* that quantify adverse effects caused through entire and complex exposure patterns. Special emphasis is on the toxicity data needed to reliably calibrate the models. Modelling results showed a broad variation of predicted effects strongly depending on the specific exposure patterns of a plant protection product. Another focus of this contribution is the presentation of semi-field growth data *of M. spicatum*. The monitoring of plant growth was initiated to identify the spatial capacity limit of plant growth and to obtain long-term growth data that are otherwise hardly available for aquatic macrophytes. The maximum capacity of total plant length was approximately 150 m for the containers with their specific spatial dimensions.

Plant community modelling as a means to assess herbicide effects on plant reproduction using the IBC model approach

J. Reeg, University of Potsdam / Plant Ecology and Nature Conservation; T. Schad, T. Preuss, Bayer CropScience / Environmental Modelling; C. Mihan, Bayer CropScience AG; F. Jeltsch, University of Potsdam

Risk assessments of plant protection products include testing effects on non-target terrestrial plants (NTTPs). To address the protection of plant communities at landscape level, several researchers state that the full plant life cycle should be assessed, since reproductive endpoints (e.g., seed production and germinability) may be more relevant for the continuation of the populations. It remains unclear, which effect extent might be tolerable to still preserve plant populations. During a follow-up SETAC workshop on NTTPs held in Wageningen on September 21 and 22 2015, the need for reproductive studies was discussed and extrapolation from existing studies appears meaningful. The framework of Xplicit-IBC offers an excellent opportunity to address this task. It aims to analyze herbicide drift effects on non-target terrestrial plant communities and populations within a landscape community context by utilizing an individual-based spatiotemporally explicit plant community model (IBC-grass). IBC-grass is an individual-based stochastic plant community model for grasslands using the plant functional type approach to cover a wide range of species. It was parameterized for a typical herbaceous field boundary community in Europe. The regional species pool was based on an extensive literature research and was classified into plant functional types (PFTs). Due to the individual-based approach of IBC-grass, we were able to address potential herbicide effects on relevant reproductive attributes of plant individuals. In a first model test phase, we conducted unrealistic worst-case simulation experiments in which we differentiated the relevant attribute(s), effect extents and the affected PFTs. These simulations indicate that effects on reproductive endpoints can have complex impacts on PFT populations. Individual-based plant community modelling can provide valuable tools to clarify the need and - if necessary – the design of future experiments. Further investigations will analyze in greater depth the dependency of effects on plant trait characteristics (e.g. type of reproduction) and the sensitivity of potential endpoints. In these studies herbicide exposure will be simulated in a more realistic pattern to investigate real-world situations (e.g., variable herbicide exposures) and will be upscaled to a landscape level by integrating the herbicide exposure model Xplicit.

Metals in the Environment: Fate, Speciation and Bioavailability in Water, Soil and Sediment (I)

24

Modelling chromium(III) binding to humic substances and its speciation in soil solution

J.E. Groenenberg, Alterra Wageningen University and Research Centre / sustainable soil management; E. Temminghoff, Wageningen University / Soil Quality

Chromium exists in natural environments in the Cr(III) and Cr(VI) redox state. Humic substances can reduce the more toxic Cr(VI) to Cr(III). Cr(III) binds very strongly to organic matter in soils which reduces its availability and protects it against oxidation. Binding of Cr(III) to humic substances is however hardly quantified and binding constants for Cr binding to humics in ion binding models are based on very limited experimental data. Modeled Cr(III) speciation in soil solution using the NICA-Donnan model in combination with generic model parameters deviated strongly from speciation measurements in soil solution extracts with the Donnan Membrane Technique (DMT). To quantify Cr binding to humics we studied the binding of Cr to an isolated fulvic and humic acid using the DMT. Based on these results new model NICA-Donnan model parameters for Cr binding to humics were derived, using the coupled PEST-ORCHESTRA modeling tool. Additional information other than macroscopic adsorption data were nescessary to make scientifically sound choices with respect to the parameterisation.

Understanding the behaviour of silver in surface and wastewater environments: Experimental validation of WHAM

A. Peters, wca; G. Merrington, wca consulting; R. van Egmond, Unilever; S.D. Smith, Wilfrid Laurier University / Department of Chemistry; S. Lofts, Centre for Ecology & Hydrology / Shore Section

Exposures to ionic silver are known to result in adverse effects in laboratory test organisms at concentrations in the low parts per billion range. Yet, environmental exposures are rarely in the ionic form and so are less ecotoxicologically relevant. It has long been established that dissolved organic carbon (DOC) and sulphur compounds in freshwater and effluents can bind with silver mitigating ecotoxicity and influencing the behaviour and fate. Concentrated samples of natural organic materials were collected from four freshwater sites in Canada using reverse osmosis. Standard samples of natural organic matter (NOM) concentrates, collected using a similar reverse osmosis method to that employed for the field samples, were also obtained from the International Humic Substances Society (IHSS). The sludge from a raw sewage sample was also tested as a binding matrix.Silver binding to the organic matter concnetrates, including raw sewage, was determined by titration using a silver ion selective electrode. Organic matter samples showed varying levels of silver binding at the same metal to carbon ratios. Various properties of the organic matter samples were determined in order to identify the factors affecting silver binding strength between different samples. The properties investigated included fluorescence, specific UV absorption, thiol concnetrations, and chromium reducible sulfide concentrations. Chromium reducible sulfide concentrations in the organic matter samples correlate with the degree of silver binding and may be used to refine WHAM predictions of silver speciation.

Electroanalytical techniques to determine free concentrations and lability degrees in Indium solutions.

J. Galceran, Universitat de Lleida / Dep Quimica; M. Heidarkhan Tehrani, A. Dago, E. Companys, J. Puy, Universitat de Lleida and AGROTECNIO / Dep Quimica

Indium is a critical element present in electronic devices, from which it can eventually leach to natural waters. The large hydrolysis processes of Indium (e.g. an increase by 0.1 units in pH in precipitated systems decreases the free concentration by a factor of 2) hinder the accurate study of its speciation and availability with most conventional techniques and, so, there are many unresolved aspects of the behaviour of free Indium in various systems[1]. AGNES (Absence of Gradients and Nernstian Equilibrium Stripping) is an emerging electroanalytical technique designed to determine free metal ion concentrations in solutions, such as seawaters, river waters, dispersions of nanoparticles, extracts of soils, etc (see recent review[2]). The implementation of AGNES with mercury electrodes requires amalgamating elements such as Zn, Cd, Pb, Sn or In. Due to some irreversibility of Indium on the Hg electrode, a new calibration strategy has been developed. Speciation results in the system Indium+Nitrilotriacetic acid with AGNES agree with computations using database NIST 46.6. However, the evolution of free Indium for increasing amounts of the ligand oxalate indicates that the values of the stability constants in NIST 46.6 [3] are not so accurate as those of Vasca *et al*.[4]. A new strategy, called Accumulation under Diffusion Limited Conditions (ADLC), can be applied to compute the lability degree of the complexes. The lability degree is strongly linked to the availability of this element as it describes the contribution of the complexes to the overall uptake flux. The use of highly labile complexes (such as those of oxalate) allows for a dramatic reduction of the deposition times, especially for huge gains (i.e. preconcentration factors). For instance, in the system oxalate+In at pH 3, equilibrium for a gain larger than 300000 was attained in just 25 seconds retrieving $[In^{3+}]=3.71\times10^{-10}$ M. In precipitated solutions at pH 5.6 (where the free Indium concentration is fixed despite the addition of the helping oxalate), $[In^{3+}]= 1.87\times10^{-11}$ was determined. Colloidal metal speciation in historically contaminated sites studied using centrifugal FFF

G. Cornelis, University of Gothenburg / Department of Chemistry and Molecular Biology; . LÃv, Swedish University of Agricultural Sciences; J. Gustafsson, KTH royal Institute of Technology / Land and Water Resources Engineering; M. Hassellov, University of Gothenburg / Department of Marine Sciences; D. Berggren Kleja, Swedish University of Agricultural Sciences

Many indications exist that natural colloids are often vectors for many metals, predicting large discrepancies between modelled and experimental results, particularly for those metals having relatively high partitioning coefficients (K_d values), such as lead (Pb). Centrifugal Field flow fractionation (cF^3)and sequential filtration wereused to analyse the colloidal speciation of several metals released during unsaturated leaching of intact cores of historically contaminated sites in an irrigation chamber. It was also investigated whether this speciation changes during simulated extreme rainfall events. cF^3 ♀_ ICP-MS complemented sequential filtration data the former technique gave a much more detailed picture of the association between several elements simultaneously. Most metals of interest were found as dissolved species and/or associated with relatively small colloids (< 200 nm). The speciation of lead was spread over iron oxides, organic matter and an aluminium bearing phase, but it was unclear whether the latter phase was a clay fraction or aluminium oxides. Sb occurred in relatively larger particles only in one particular soil from an industrial area without associations with other elements. As and Cr appeared mainly dissolved, but partly associated with iron oxides. Differences between the two rainfall scenarios were, in general, limited. The division of metals over dissolved phase and differently size colloids has implication for modelling their fate and bioavailability in realistic systems,

because K_d values may not always provide the most accurate prediction. The relative importance of a kinetic *versus* thermodynamic approach is discussed.

28

Specific parameterization of WHAM improves the prediction of copper competitive binding on plant roots

S. Guigues, M. Bravin, CIRAD; C. Garnier, Universite de Toulon; E. Doelsch, CIRAD

The relevance of the default humic acid (HA) in the Windermere humic aqueous model (WHAM) for modelling the binding of metal cations such as copper exhibiting high affinity for plant roots is questionable. We thus compared the ability of the default parameterization of WHAM and a specific parameterization for terrestrial higher plants (WHAM-THP) to model the competitive binding of copper on wheat (*Triticum aestivum* L.) and tomato (*Solanum lycopersicum* L.) roots. WHAM overestimated by twofold the binding of copper on roots under varying ionic strength and concentration of competitive cations (proton, calcium, and zinc). With a single set of parameters for both wheat and tomato, the specific parameterization of WHAM-THP improved the goodness of the fit of copper competitive binding ($\log_{10}$ of the root-mean-squared residual = 0.15) without any systematic bias. We put forward proposals for the practical application of WHAM-THP in predictive ecotoxicology.

29

Speciation and localisation of gadolinium in root tissue of Zea mays

J. Saatz, Analytical Chemistry; H. Stryhanyuk, Helmholtz Centre for Environmental Research   UFZ / Isotope Biogeochemistry; B. Daus, Helmholtz Centre for Environmental Research   UFZ / Analytical Chemistry; T. Reemtsma, Helmholtz Centre for Environmental Research

The group of rare earth elements (REE) consists of 17 economically critical elements, the lanthanides and Sc and Y. Their physico-chemical properties make them useful for many high tech applications. The lack of economic recycling ways might result in the accumulation of REE in the environment, which might negatively affect organism like plants as primary producers. Bioavailability of REE was shown to be high, especially for fine ground materials like tailings [1]. Earlier studies [2] also showed high concentrations of Gd in the root tissue, with low transport to shoot tissue, therefore, speciation and localisation of Gd in root tissue was conducted. Tof-SIMS, as a surface analytical technique, offers high sensitivity and can generally detect all elements and isotopes. Gd was chosen for a hydroponic solution culture using a culture crop *Zea mays* (cv. Ronhaldino). It was applied in a concentration of 10 mg L^{-1} as nitrate. The plants were grown in a greenhouse in eastern Germany during the warm and sunny month April. After 14 days the plants were harvested. The roots were used for the investigations presented here. Thin sections ranging between 8 and 20 μm were analysed for the location and species of Gd by ToF-SIMS (ION TOF). Total concentrations of dried bulk samples were measured by ICP-MS (Agilent 7700) after digestion. High content of Gd was found in the dried bulk samples of the roots after aqua regia digestion, 8.43 ± 0.95 g kg^{-1}. Gd was analysed in spots of high concentrations at the epidermis of the root. The typical isotope pattern was identified for Gd as well as for Gd species bound to oxygen. The expected Gd-phosphates could not be found in these spots. The occurrence of the spots in the outer epidermis might be an explanation for the low transfer rates. For the first time, ToF-SIMS analysis with a spatial resolution of 4 μm was used to locate these spots and give information about the species of the Gd in the plant root. 1. Natural toxins: an on-growing challenge for environmental research, monitoring and management

30

Cyanobacterial toxins: from genome mining to risk assessment

C. Pancrace, J. Humbert, Institute for Ecology and Environmental Science - Paris / Community diversity and ecosystem functioning; M. Gugger, Institut Pasteur / Microbiologie   Collection des Cyanobactéries

Cyanobacteria are photosynthetic prokaryotes proliferating in many ecosystems worldwide. This phylum is also known to produce a wide range of bioactive natural products, notably cyanotoxins linked to animal deaths and human health hazards through drinking and recreational waters. Cyanobacterial natural products are complex peptides, polyketides and hybrid metabolites such as the well-studied hepatotoxin microcystin. Current strategies for cyanotoxin-related risk assessment are based on detection of the known producers or of the already characterized toxic compounds. This strategy does not take into account the larger cyanobacterial potential recently uncovered with genomic and metagenomic as well as metabolomic analysis. Furthermore, emerging toxins are not monitored or regulated. We studied the bloom-forming genus *Planktothrix* genetic potential dedicated to the biosynthesis of natural products. Diversity and distribution was established by *in silico* genomic analysis of newly sequenced isolated strains of diverse origin. Natural products were also characterized by mass spectrometry analyses to detect variants of the known peptides and novel natural products of this cyanobacterial genus. This multidisciplinary analytical approach could be broaden and extended with molecular biology tools for early detection of toxic potential of HABs in environmental samples. Most of the time even in the case of known compounds such as the toxin microcystin, the cellular and ecological function of the metabolite remains unknown. The understanding of regulation of natural product synthesis, as well as the cyanoHABs internal population regulation is only at its first steps. The use of genome mining strategies on NGS environmental and experimental data will lead to a more systematic survey of potential hazards. Although challenging, closing this knowledge gap between producers and their genetic potential, regulation and metabolites detection will give rise to a better risk assessment in freshwater ecosystems.

31

Structure-dependent effects of selected cyanobacterial peptides on innate immunity

O. Adamovsky, Masaryk University, Faculty of Science, RECETOX / Research centre for toxic compounds in the environment RECETOX; Z. Moosova, L. Blaha, Masaryk University, Faculty of Science / Research centre for toxic compounds in the environment RECETOX

Cyanobacteria produce many biologically active metabolites synthesized via nonribosomal synthetic pathways. These are classified into several families, according to their structural features, and include also cyclic microcystins (MCs) and linear aeruginosins (AURs). Although MCs are toxicologically known for their hepatotoxic effects, their immunomodulatory potential is not known. In contrast, aeruginosins have been studied in much lesser extent but recently isolated new aeruginosin-865 (AUR865) showed some anti-inflammatory potential. The present study aimed to investigate in detail the effects of three different MC variants and AUR865 on macrophages, which represent one of the key effector cells within the innate immune responses. Specifically, our study includes investigation and comparison of several structurally different cyanobacterial peptides on macrophage activation, associated with production of cytotoxic and cytostatic products such as nitric oxide (NO), as well as proinflammatory mediators (e.g. tumor necrosis factor α, TNFα and interleukin 6, IL-6). Although MC-LR was able to significantly affect the macrophages, other most common MCs (-RR, -YR) and AUR865 did not alter immune responses. Our recently published results on affected molecular pathways (doi: 10.1021/acs.est.5b02049) provide an interesting mechanistic explanation of some adverse health outcomes associated with toxic cyanobacteria. The research was supported by the projects of the Czech Ministry of Education LO1214 and LM2011028, and by the CYANOCOST action (EU COST ES1105).

32

Occurrence of emerging marine toxins in coastal areas of the Catalan coast

C. Bosch, IDAEA-CSIC / Environmental Chemistry; J. Sanchís, IDAEA-CSIC / Water and Soil Quality Research Group; M. Farre, IDAEA-CSIC; D. Barcelo, IIQAB-CSIC / Dept Environmental Chemistry

Marine toxins are natural substances synthetized by phytoplankton and other organisms. Main concern about these compounds is due to its potential toxics effects, especially when a harmful algal bloom (HAB) takes place. During this phenomenon, high amounts of toxins are generated; its accumulation in the particulate can favour the eutrophication of the waters and on the other hand, zooplankton, fish and shellfish that can suffer intoxication with poisoning or lethal effects. Moreover, it has been evidenced that the concentration of toxins can bioaccumulate along the food chain, supposing a potential risk for human health. Monitoring of these compounds has become an important issue during last decades. New analytical methodologies are required with the aim of determining the distribution, transport and behavior of marine toxins with enough accuracy and sensitivity. In this study, an analytical methodology has been developed and validated for the detection of different families of the most frequent marine toxins in seawater and estuarine areas. This method is based in solid phase extraction (SPE) followed by high performance liquid chromatography (HPLC) coupled to high resolution mass spectrometry (HRMS). In order to assess the occurrence and distribution of these marine toxins, the developed methodology has been applied in real samples from the western Mediterranean Sea and the Ebro's delta basin. Samples were collected in the same areas for different periods of time in order to characterize the occurrence of marine toxins in different seasons. Preliminary results show the presence of some marine toxins in similar concentration for all seasons and in non-algal bloom conditions. These results highlight the importance of further studying the degradation patterns, distribution and chronic toxic effects of these substances in order to properly carry out a risk assessment.

33

Characterization of the voltage-gated sodium channel and its isoforms in the Pacific oyster Crassostrea gigas: link with its sensitivity to paralytic shellfish toxins produced by Alexandrium minutum

F. Boullot; H. Hégaret, LEMAR UMR 6539 CNRS/UBO/IRD/Ifremer / UMR CNRS Ifremer IRD UBO; J. Castrec, LEMAR UMR 6539 CNRS / UMR CNRS

UBO IRD Ifremer; A. Bidault, P. Boudry, LEMAR UMR 6539 CNRS/UBO/IRD/Ifremer / UMR CNRS UBO IRD Ifremer; P. Soudant, C. Fabioux, LEMAR UMR 6539 CNRS/UBO/IRD/Ifremer
French coasts are regularly affected by blooms of the dinoflagellate *Alexandrium* spp. These micro-algae can produce paralytic shellfish toxins (PST), such as saxitoxin (STX) and its derivatives, which bind to voltage-gated sodium (Nav) channels and block conduction of action potential in muscle and nerve fibers. Filter feeder marine organisms, such as oysters, can accumulate high levels of PST, making them toxic and unsuitable for human consumption. The toxin load in *Crassostrea gigas* oysters, has been shown to vary between individuals, sampled from a same population and then exposed experimentally to *A. minutum*. These results suggest a high variability in PST tolerance. The purpose of our study was (i) to characterize Nav channel and its isoforms in *C. gigas* and (ii) to determine whether Nav channel isoforms play a role in the sensitivity of *C. gigas* to PST. The tissular and cellular expression pattern of Nav was characterized by real-time PCR and *in situ* hybridization. Nav appeared mainly expressed in neurosecretory cells of the visceral ganglia, in nerve fibers of the striated muscle and in epithelial cells of the labial palps and mantle. First sequencing analysis of Nav cDNA in muscle and visceral ganglia revealed three alternative splicing transcripts. These transcripts have a specific tissular expression. Only one transcript is found in the striated muscle, whereas the two other transcripts are expressed in the visceral ganglia. This alternative splicing could be a source of the differential sensitivity to PST in *C. gigas*, as demonstrated in some insects for resistance to pyrethroids, and consequently could lead to variable toxin load in oysters exposed to *A. minutum*. As a result, we will analyze the presence/absence of each splicing variant as well as their expression level in muscle and visceral ganglia in oysters experimentally exposed to *A. minutum* to test the correlation between Nav variant expression and toxin accumulation.

34
Identifying phytotoxins of environmental concern
T. Bucheli, Agroscope ART / Environmental Analytics Natural Resources and Agriculture; J. Hollender, Eawag / Environmental Chemistry; M. Scheringer, K. Hungerbuehler, ETH Zurich / Institute for Chemical and Bioengineering
Today, environmental scientists, regulators and decision makers are well aware of the presence and potential risk of anthropogenic chemicals in the aqueous environment. In contrast, natural toxins from plants (phytotoxins) have not yet been perceived as potential aquatic micropollutants. A number of arguments lead us to hypothesize that phytotoxins might indeed play a role in this respect, the most important of which are: 1) there are thousands of toxic plants, containing a variety of even more chemically very diverse phytotoxins, 2) exposures in anthropogenically managed/affected (agro-)ecosystems can be orders-of-magnitude higher than in the pristine environment, 3) phytotoxins are toxic by definition, although their mode of action is often unknown, 4) effects of phytotoxins (on non-target organisms) have been shown in case of allelochemicals, invasive plant species, and biopesticides, and 5) to properly evaluate the risks of (emerging) anthropogenic contaminants, the background stress/toxicity potentially exerted by natural toxins should be known. Therefore, we propose a systematic assessment of the aquatic environmental exposure to phytotoxins in Switzerland. This is accomplished with a sequence of iteratively refined work packages, including: 1) compilation of a database of phytotoxins, based on the spatial distribution and chemical fingerprint of toxic plants in Switzerland, 2) elucidation of physicochemical properties of phytotoxins using literature data or in silico estimations, 3) prediction of the phytotoxins' environmental fate and behavior and likely recipient matrices by means of in silico multi-compartment mass-balance models, 4) surface water sampling in collaboration with respective monitoring networks, and 5) target and suspect analysis of phytotoxins in the collected water samples. This way, we aim to identify among the many thousands of phytotoxins those – probably rather few – that actually may be considered as aquatic micropollutants.

35
Environmental fate and ecotoxicological impact of leptospermone, a natural β-triketone herbicide in soils
l. barthelmebs; S. Romdhane, University of perpignan / CRIOBE BAE; M. Devers-Lamrani, INRA Institut National de la Recherche Agronomique / UMR Agroecologie; C. Calvayrac, University of perpignan / BAE; F. Dayan, Colorado State University / BSPM; C. Bertrand, Université de Perpignan / CRIOBE; J. Cooper, University of perpignan / CRIOBE; I. BATISSON, CNRS-Clermont Université, Université Blaise Pascal / Laboratoire Microorganismes Génome et Environnement; F. Martin-Laurent, INRA / Agroecologie
Most agricultural production relies on the use of chemicals to maintain high crop yields. The use of these chemicals in farming practices is viewed as an integral part of the success of the intensive farming. However, most of the pesticides applied to agricultural lands may affect non-target organisms and contaminate soil and water media. Increasing public concern about the impact of pesticides on the environment, and European legislation has led to develop some strategies to evaluate and to prevent the potential impacts of different land management practices. In this context, new generations of less environmentally dangerous molecules, such as lower impact pesticides, biopesticides and natural product-based pesticides have been introduced. Despite this, a lot of work has to be carried out to evaluate the possible risks and adverse effects of such compounds on environment and humans. In the frame of the TRICETOX project, we study the β-triketone herbicide family, a post-emergence maize selective herbicides belonging to this new generation of molecules. Inside this family, we focus on leptospermone, an allelopathic compound isolated from the bottlebrush plant *Callistemon citrinus*. Since few data are available for this molecule, we want to gain new insights by addressing its soil behaviour, by studying its impact on soil microbial communities, by studying its biotic and abiotic degradation and by testing its toxicity. Then, multidisciplinary approaches were applied to assess the fate and impact of leptospermone in two different soil types. Our results showed that in the two tested soils, leptospermone has a similar fate to that of the synthetic β-triketone herbicides, such as sulcotrione or mesotrione. Interestingly, leptospermone exhibits a 10 fold lower toxicity, determined with Microtox^R than the two synthetic counterparts. Although leptospermone was rapidly dissipated from soil, it has a significant ecotoxicological impact on the abundance and diversity of soil bacterial community. This ecotoxicological impact was transient and when leptospermone was fully dissipated, the bacterial community recovered its initial composition and diversity. However, the recovery cannot be reached in soil microcosms where leptospermone remained. Characterization of a bacterial isolate able to degrade leptospermone is in progress. Further work need to be done to test the ecotoxicological impact of this natural β-triketone on a wider range of soil classes.

Advances in exposure modelling: bridging the gap between research and application (I)

36
Screening level Environmental Exposure modelling Of Engineered Nanoparticles: An analysis using SimpleBox4nano
J. Meesters, Radboud University Nijmegen / Environmental Science; D. van de Meent, Radboud University / Department of Environmental Science
In order to sustain the development of nanomaterials by industry, a robust risk assessment framework is needed. A screening level environmental exposure model is one of the first steps of such a framework currently in place in Europe and the United Sates, but this needs adaptation for use with nanomaterials . For this reason, SimpleBox4nano was developed as a first step in developing a screening level exposure model that can be used as part of such risk assessment frameworks currently in place for conventional chemicals. Here we present a further analysis of the SimpleBox4nano model in order to continue its development towards a robust screening level exposure assessment model for nanomaterials. First an analysis is done of the uncertainty and variability in output exposure concentrations of three metal oxide ENPs (TiO_2, ZnO and CeO_2) in relation to the uncertainty and variability of the emission rates and a broad selection of input parameters, including environmental properties such as e.g. ambient particle concentrations and temperature. Second, a sensitivity analysis is done for the nano-specific properties: nanoparticle size, density, dissolution rate and attachment efficiency while still accounting for variability of the environmental properties in order to more clearly understand the significance of these specific nanomaterial properties compared to natural variability.

37
A Kinetic Environmental Fate Model for the Risk Assessment of Engineered Nanomaterials
J. Perez Holmberg, University of Gothenburg / Chemistry and Molecular Biology; R.F. Domingos, Institut de Physique du Globe de Paris / Équipe de Géochimie des Eaux; C. Svendsen, CEH, Wallingford / Pollution and Ecotoxicology; E. Dumont, CEH Wallingford; M. Matzke, Centre for Ecology & Hydrology (NERC) / Molecular Ecotoxicology; R. Vanhauten, ThinkWorks B.V.; S. Lofts, Centre for Ecology & Hydrology / Shore Section; V. Keller, Centre for Ecology & Hydrology; G. Cornelis, University of Gothenburg / Department of Chemistry and Molecular Biology
An integrated exposure model is proposed for the prediction of the environmental fate of nanomaterials (NMs) in various natural and man-made compartments. A semi-mechanistic approach is used, wherein the kinetic nature of the NM fate processes takes focus. Environmental matrix interactions depend on NM properties and relevant parameters, such as organic matter and ionic conditions, and are calculated on a temporal scale in each compartment. The risk quotient is calculated based on the maximum calculated temporal NM bioavailability and existing hazard information. The goal of this approach is to apply the model for most currently-produced and possible future NMs, also aiming to find a compromise between mechanistical accuracy and operational simplicity. In the current model, fate descriptors are detailed for the following compartments: soil, surface water, sediment and wastewater treatment plant (WWTP). The WWTP is the main entry point for NMs emitted with domestic and industrial liquid waste. Partitioning of NMs in the WWTP, based on their affinity to sludge, determines the amounts that are transported to the surface water (in the effluent) and the soil (via sludge). The physicochemistry of the surface waters, including fresh-, estuarine-, and marine water, and the properties of the NM are among the factors

that affect its bioavailable concentration in the water column and, after possible sedimentation, in the sediment within a certain time. The kinetic model includes rates of the following key processes: dissolution, sulfidation, heteroaggregation, and sedimentation. NMs arrive in topsoils via the annual deposition of sludge. The time-dependent concentration in the pore water (liquid phase) and on the soil material (solid phase) is determined using a dual deposition model, allowing both NM release and (ir)reversible attachment. The time-dependency of chemical species concentrations is essential since it evokes realistic time-dependent exposure scenarios whereas available hazard values are almost always considered static. This information is relevant in assessing the bioavailability and eventual risks of NM release and transport. This kinetic fate model is a key component in the web-based tool for the assessment and management of risks associated with NM-enabled consumer products, under the GUIDEnano Project (EU FP7). This work also contributes to the NanoFASE Project (EU H2020).

38

The importance of temporal variables in environmental modelling: Rationalizing measured concentrations of cyclic volatile methyl siloxanes in an Arctic lake

I.S. Krogseth, Norwegian Institute for Air Research / Environmental Chemistry; M. Whelan, University of leicester / Geography; G. Christensen, A. Evenset, Akvaplan-niva AS; K. Breivik, Norwegian Inst. for Air Research; N.A. Warner, NILU - Norwegian Institute for Air Research / Environmental Chemistry

Cyclic volatile methyl siloxanes (cVMS) are used in personal care products and are emitted to aquatic environments through wastewater effluents. In this study, we describe a holistic evaluation of the environmental fate of cVMS in an Arctic lake (Lake Storvannet, 70 °N 23 °E) experiencing seasonal variations in environmental conditions and intermittent wastewater emissions. Sewage, lake water, and sediment samples were collected and analyzed for cVMS concentrations in 2014. While measured cVMS concentrations in lake water were below detection limits, concentrations in sediments were comparable to concentrations observed in higher populated areas. To rationalize measurements, Mackay et al.'s QWASI-model was parameterized for Storvannet and run for steady-state conditions assuming constant emissions and under dynamic conditions accounting for temporally variable emissions, water-flows, temperatures and ice-cover. Inverse modelling was employed using the steady-state QWASI to estimate the average rate of emission from the measured concentrations of cVMS in sediment. This resulted in a significant over-prediction of cVMS concentrations in water compared to actual measurements and to unrealistically high emission estimates to the lake based on measured concentrations in sewage. The dynamic model could mechanistically rationalize high (and relatively stable) concentrations of cVMS in sediment and low concentrations in the water column by employing a hypothetical intermittent emission scenario consistent with combined sewer overflows and a lower annual average emission. In both the steady-state and the dynamic scenarios, the most important removal process for cVMS from lake water was predicted to be advection due to the high rate of water-turnover, while removal processes typically dominant in other aquatic systems were limited in Storvannet due to low temperatures, ice-cover and slow sedimentation rates. This study illustrates the benefits of combining monitoring with models as interpretive frameworks to understand the environmental behaviour of organic contaminants, and the need to balance simplicity and complexity in modelling efforts. In addition, the insight gained on the fate of cVMS in Arctic environments may be useful for interpreting biotic exposure in Arctic environments and may inform ongoing regulatory debates for cVMS materials.

39

Can eutrophication impact air-sea exchange and concentrations of contaminants in marine systems?

E. Undeman, Stockholm University / Environmental Science and Analytical Chemistry ACES; K. Dahlgren Strååt, Stockholm University / Department of Environmental Science and Analytical Chemistry ACES; E. Gustafsson, Stockholm University / Baltic Sea Centre; B. Gustafsson, Stockholm University / Baltic Nest Institute Baltic Sea Centre

Eutrophication impacts not only biogeochemical and ecological processes in many water bodies, but potentially also the distribution and degradation of many organic contaminants since these substances have a tendency to partition into organic phases. A number of hypotheses for interactive mechanisms between contaminants and eutrophication have been postulated. One important mechanism is the removal of chemicals from the atmosphere via the so called biological pump. How the importance of this and other processes related to the marine carbon cycling varies with the inherent properties of the chemicals has, however, yet not been evaluated. In this study we use a modeling tool with multi-stressor functionality (Baltsem-POP) to assess how changes in nutrient input and the subsequent changes in primary production may influence concentrations and total input of organic contaminants in marine systems such as the Baltic Sea. The average concentrations and fluxes of a wide range of organic contaminants in the Baltic Sea by the end of this century were predicted to differ by at most a factor of 2 when comparing a plausible future eutrophic and a more oligotrophic system. Whereas eutrophication increased or did not change total input from the atmosphere for all compounds, dissolved concentrations in the eutrophic system were always lower or not impacted for all modelled chemicals. The predicted chemical mass stored in the active sediment layer was not consistently positively or negatively influenced by increased primary production across the chemical space, instead reflected the combined influence of increased atmospheric input and depleted surface water concentrations. We found that mitigation of anthropogenic eutrophication may increase dissolved concentrations of many compounds with relatively low volatility in surface waters, but at the same time lower the total input from the atmosphere of more volatile hydrophobic contaminants and consequently their accumulation in sediments.

40

Integration of environmental and human PBPK exposure models: application of MERLIN-Expo modelling tool to POPs exposure in Venice lagoon.

A. Radomyski, University of Venice / Department of Environmental Sciences Informatics and Statistics; E. Giubilato, A. Critto, University Ca Foscari of Venice / Department of Environmental Sciences Informatics and Statistics; P. Ciffroy, Electricitè de France / LNHE Department I; C. Brochot, INERIS / Models for Ecotoxicology and Toxicology METO; A. Marcomini, University of Venice / Department of Environmental Sciences Informatics and Statistics

MERLIN-Expo is a new tool for integrated exposure assessment recently developed under the FP7 project "4FUN". MERLIN-Expo is a simulation platform providing a library of multimedia and physiologically-based pharmacokinetic (PBPK) models which can be coupled in order to estimate ecological and human exposures in complex scenarios. Models can be used to simulate fate of organic (PAHs, PCBs) and inorganic contaminants. Software enables end-user to apply set of functionalities such as uncertainty and sensitivity analysis, dynamic deterministic and probabilistic simulations in order to address different exposure and chemical fate problems. MERLIN-Expo was applied to assess the ecological and human exposure to PCBs and PCDDs in the Venice lagoon. The Phytoplankton, Aquatic Invertebrate and Fish models were developed and implemented in MERLIN-Expo library, subsequently integrated to create specific aquatic food web to dynamically simulate bioaccumulation in different aquatic species. Concentrations of PCBs and PCDDs in water were used as time-dependent inputs to run long term simulations. The estimated concentrations in edible aquatic species were then used to estimate daily human intake through the consumption of local seafood. The application of the PBPK model allowed to explore the time dependent accumulation of target chemicals in human tissues for several decades. Modelling results are tested against available monitoring data on chemical concentrations in edible aquatic species and concentrations in serum of adult men in Venice area to assess the reliability and applicability of the proposed tool to real complex scenarios. Full chain exposure assessment is then complemented by uncertainty and sensitivity analysis including local sensitivity methods, screening methods (e.g. Morris method), global regression methods (e.g. Standardised Regression Coefficients), and global variance based methods (e.g. FAST, EFAST, Sobol). These methods allow to follow for instance WHO (2008) recommendations to perform three stage uncertainty/sensitivity analysis, adopting qualitative, semi-qualitative, and quantitative methods. Integration of environmental and human exposure models in MERLIN-Expo allows comprehensive assessment of exposure and thus better characterisation of overall risk to human and environment especially in the case of higher tier assessment. This makes the tool interesting and promising for potential applications in different regulatory domains.

41

Quantifying the Near-Field Exposures to Chemicals in Flooring Materials during the Use Phase

L. Huang, University of Michigan / Dept of Environmental Health Sciences; O. Jolliet, University of Michigan

There is growing evidence that near-field chemical intakes during use phase could be as important as environmentally mediated exposures. Thus, it is crucial to consider the exposures during the use phase when assessing the potential human exposures from consumer products. Chemicals encapsulated in products can be a major emission source in the indoor environment and in the use phase, of which typical examples are chemicals in flooring materials. These chemicals can be released to indoor air leading to inhalation exposures, and can also migrate to the flooring surface and lead to dermal exposure via physical contact. The present study thus aims to characterize the near-field exposures from chemicals encapsulated in flooring materials. A parsimonious model which describes the diffusive emissions of chemicals from materials and the subsequent loss by ventilation was employed. This model can predict the fraction of chemical mass emitted to air and the chemical concentration on product surface using two exponentials. The predicted air emissions and surface concentrations are then multiplied by an indoor inhalation intake factor and a skin permeability coefficient, respectively, to calculate the product intake fractions (PiFs), which determine the fraction of a chemical in a product that is taken up by humans during its use phase. The exposure doses can then be obtained by combining the PiFs and the chemical content in the product. Chemicals studied include 13 chemicals (5 SVOCs and 8 VOCs) in flooring that have ToxCast Oral Equivalency Dose (OED) data. PiFs were calculated for a child under 5-yr old in a

typical North American household with 3mm-thick flooring. Two extreme times points were chosen: 50 days and 15 years. All compounds have inhalation intake dominating except Bisphenol-A, whose dermal intake dominates. VOCs generally have higher exposure doses than SVOCs. Average daily dose ranges from 10^{-4} to 10^{1} for the first 50 days of flooring use and from 10^{-4} to 10^{-1} for 15 years. The exposure doses for most chemicals over 15y years are below OEDs, while half chemicals have doses higher than OEDs during the first 50 days, demonstrating the importance of the time scale when assessing exposure doses. This study shows that chemicals in flooring materials can lead to significant near-field human exposures, especially during the initial period (first 50-100 days) of flooring use, and further investigation is warranted.

Life Cycle Data and Modeling Developments - From Data Collection to Usage (I)

Towards a Global Network of Interoperable LCA Databases

L. Mila i Canals, UNEP; F. Wang, United Nations Environment Programme (UNEP) / SCP; A. Ciroth; S. Fazio, EC-JRC / Institute for Environment and Sustainability; M. Goedkoop, PRe Consulting; W. Ingwersen, US EPA; S. Suh, University of California Santa Barbara; K. Tahara, Research Institute of Science for Safety and Sustainability; J. Tivander, Chalmers University of Technology / Environmental Systems Analysis Energy and Environment; B.W. Vigon, SETAC; G. Wernet, ecoinvent Centre; T. Braga, C. Leite, IBICT

1. Introduction International LCA dialogue has been formalized between countries within The "International Forum on LCA cooperation" since 2011 in order to facilitate the implementation of Sustainable Consumption and Production policies. Within this dialogue, cooperation on and access to global data has been identified as a must in order to reduce the cost and increase applicability of LCA studies in a context of a global economy. Therefore, the countries, with the support of UNEP, launched the Global Network of Interoperable LCA databases (the "Global Network") and agreed on a shared ambition that by 2017 the LCA user has a global and easy access to the main LCA databases with assessment of "fitness for purpose". 2. Materials and methods The Steering Committee is the governance body of the initiative and it is supported by the working groups, who are the operational units, created for a limited duration and focused on particular tasks products and deliverables. Three working groups (WG) have been launched: i) "Network Architecture and Technology" ii) "Nomenclature and iii) "Metadata descriptors". Working groups are co-chairs by experts and gather more than 50 experts worldwide. Each working group has defined a workplan, timeline and corresponding budget for the duration of the project. 3. Results This presentation will provide the latest update following up the 2016 face-to face meeting, scheduled in Brasilia from 14 to 16 March 2016. As of now, the following deliverables are planned to be completed: **Network Architecture and Technology** Review of existing examples and technologies for interoperable databases Development of functional requirements of the interoperable network of LCA data First discussion on a list of viable network options **Nomenclature** Agreed elementary flows mapping file ready for review Critical review of existing nomenclature mapping systems **Metadata descriptors** Identification of data quality assessment needs, with a focus on meta-information **\n** 4. Conclusion In conclusion, enhanced data accessibility and interoperability will benefit the whole community and the mainstream applicability of LCA, and is the foundation for key sustainability initiatives. Policy makers are relying on it for e.g. developing sound SCP policies. Industries will be able to base their innovation and strategic sustainability decisions on more robust information.

43

BONSAI recommendations and procedures for implementation of an open source database

M. deSaxce, 2.-0 LCA consultants; B. Weidema, Aalborg University; K. Stadler, NTNU; C. Davis, University of Groningen; S. Merciai, 2.-0 LCA consultants; S. Pauliuk, Albert-Ludwigs-Universität; B. Zhu, TU Delft

The BONSAI database (https://bonsai.uno) is an open source community initiative, using semantic web technology and data harvesting to increase the free access to structured LCI data. This presentation describes our recommendations and current work on implementing the BONSAI core database and system. We implement the core database as an RDF store. The RDf store is designed for storing supply-use data, defined as a flow-by activity matrix for the balanceable properties of flows between activities, further specified by location, time and macro-economic scenario (relevant for forecasted data). Each datapoint consists of a value together with an unit and an uncertainty estimate. Non balanceable flow-properties and metadata can also be stored with the supply-use framework. We recommend a separate matrix to store information on complementary and substitutability between products. Besides the core database, BONSAI will store algorithms and software code for estimating missing data, automatic data harvesting and accessing and data manipulation. From the supply-use data, the algorithms will allow the calculation of direct requirements tables and their Leontief inverse matrices in order to estimate the product footprints. The barrier for adding data to the BONSAI database should be kept as low as possible, and conflicting data sources allowed to co-exist. Instead, data quality should be scored and reviewed subsequently, allowing algorithms for quality-scoring and consolidation to provide tresholds for temporary inclusion/exclusion and to derive preferred datapoints.The integration of data at many different levels of detail requires algorithms for automatic disaggregation and gap-filling, using global product and activity breakdowns based on industry data sources and data from countries with detailed data. The first public beta-version should demonstrate proof-of-concept of the key aspects that differentiate BONSAI from other similar databases. This includes the modular approach to software design, the low barrier to data entry with subsequent open review, the completeness (integrating MRIO and detailed data), the natural language footprint query interface and the transparency of the underlying data and routines. This also implies that the data needs to be provided with a fully open license (CC-BY) that allows also commercial use.

44

Coupling process simulation and life cycle assessment: applications to bio-based process investigation

N. HAJJAJI; J. STEYER, Institut National de la Recherche Agronomique, Narbonne-France / UR Laboratoire de Biotechnologie de lEnvironnement; A. HELIAS, Institut National de la Recherche Agronomique, Narbonne-France

Simulation of manufacturing processes combined with environmental impact assessment gives engineers the opportunity to improve the environmental performances of the production system. Process simulation tools were used with LCA in order to study the influence of operating parameters and to estimate missing data for life cycle inventory. This work presents, through two illustration cases, the use of process software (Aspen Plus™) as a tool for inventory data estimation and for environment performance optimization. The first case illustrates the use of the software to estimate inventory data for the production process of H_2 from biogas reforming based on an anaerobic digestion plant inventory from the literature. The second example addresses an optimization of bioethanol steam reforming process to provide accurate conditions for sustainable H_2 production. A variation in process operating parameters was also performed to illustrate the environmental performance sensitivity and provide guidance as to research and development effort focus for the process improvement. The variation of the parameters was performed using two methods: intuitive approach, where the levels of all parameters are fixed except one varying, and a factorial Design of Experiments (DOE) method. The different process configurations were simulated in Aspen Plus™ to provide foreground inventory data for the LCA of H_2 production system. For both systems, H_2 from biogas reforming or from bioethanol, the substrate production greatly influences the environmental performances of the whole system, especially when the system comprises an end-of-life management scenario (first case). The second investigation (H_2 from bioethanol reforming) indicates that the increase of reforming temperature improves the environment performance of the H_2 production system. Whereas steam to carbon ratio has a marginal effect on the environment performance. The main outcome of this DOE method is the development of mathematical models that predict how changes in the reformer operating temperature and steam to carbon ratio affected the environmental performances. The systematic integration of simulation tools into the elaboration of environmental assessment of processes will bring scientific legitimacy to environmental evaluation by LCA. The simulation-based LCA can be very helpful to develop more sustainable processes and products. This axis should be further developed, for instance, by sharing the software databases.

45

LCA Cloud: enhancing LCA data collaboration

C. Rodríguez, S. Greve, GreenDelta GmbH; A. Ciroth,

Data exchange is an important concern in LCA due to the high variety of existing data formats, nomenclatures, data quality criteria, etc. Some of the mentioned challenges have been already overcome in the free, open source LCA software openLCA by integrating the most complete import and export features, which include all the commonly used LCA data formats (i.e. ILCD, EcoSpold1, EcoSpold2, etc.), as well as by the harmonization of elementary flows for the different LCI databases available in openLCA Nexus. As a further step towards facilitating LCA data creation and exchange, a new web service providing cloud functionalities was developed and integrated into openLCA. This "LCA Cloud", which was developed as part of a project supported by the US Department of Agriculture (USDA), allows the upload and download of data sets into/from a data repository. Moreover, a merge tool was also implemented in openLCA to identify and solve conflicting changes in the data sets retrieved from the server. The RESTful web service for storing and providing LCA data in a uniform way was developed as a standalone web application. The JSON ld format is used for the exchange of data between the service and the openLCA software. This format is recommended by W3C for linked data and it can directly be parsed as RDF triples and, therefore, be directly linked to ontologies. Moreover, the web service contains also other functionalities such as querying of data sets by user defined criteria, validity check to avoid corrupting databases, user and repository management systems and copyright protection procedures. Additionally to the web service, a merge tool was developed and integrated into openLCA in order to identify and manage conflicting changes to the same dataset. This functionality is specially useful when several users work in paralell in the same data. A text comparision between the two versions of the dataset is done for each of the fields included in it (e.g. descriptions, locations, amounts, units, etc.). The differences found are then displayed highlighted in the tool's editor and the user has the possibility of accepting all, part or none of the modifications addressed. "LCA Cloud" and the merge tool are powerful features for data sharing using the LCA software openLCA, which enable not only loading and retriving data from web repositories managed by the users or by external hosts but also the identification of differences within several versions of the same data set.

46
SuBoot - Sustainability Bootstrap Project
J. Hildenbrand; A. Ciroth; M. Cinelli, University of Warwick; V. Gjorgjioski, GrabIT
Oftentimes individual data collection for a case is considered as one of the more time consuming stages of a life cycle assessment, while on the other hand data is available but needs to be processed from all kinds of repositories. A novel approach to rapidly create a reliable and sound data base is tested within the SuBoot project, which is built around three key ideas. (i) The request from consumers to consider sound, reasonable information about the sustainability of products, at point of sale; (ii) .Opportunities for businesses to increase their revenues and market shares if they focus on green and ethically produced goods; Inclusion of alternative sources for sustainability information, which are "untapped" today. The aim of SuBoot is, therefore, to be a system to massively collect life cycle and sustainability data from primary sources, and make it available in supply chains and to end users: empowering consumers by providing life cycle sustainability information at the point of sale. These aspects are integrated in a smart and smooth software system, including one or several data nodes, an app for end consumers, and a B2B application. The system will be presented for a practical case to highlight challenges and solutions.

47
Water supply mix: spatial, temporal and user variability at European scale
S.O. Leão, IRSTEA Montpellier / UMRITAP ELSA; M. Núñez, National Research Institute of Science and Technology for Environment and Agriculture Irstea; P. Roux, National Research Institute of Science and Technology for Environment and Agriculture   Irstea / UMR ITAP ELSA; E. Loiseau, National Research Institute of Science and Technology for Environment and Agriculture - Irstea; Y. Penru, Suez Environnement SAS; A. Sferratore, Société du Canal de Provence et daménagement de la région provençale; G. Junqua, Ecole des Mines dAlès / LGEI; R.K. Rosenbaum, National Research Institute of Science and Technology for Environment and Agriculture - Irstea / UMR ITAP
Usually, the water used by a particular user (domestic, industrial, agriculture, etc) does not come from a single source but rather from a mix of local and sometimes imported water sources. Depending on the origin of the water abstracted (river, lake, aquifer, sea, etc), the location (water abundant or poor), the volume being extracted and the season of the year (wet/dry), the resulting environmental impacts will differ. It is therefore very important that Life Cycle Inventory (LCI) databases contain information on these aspects for proper subsequent impact assessment. However, current LCI databases neither differentiate (sub-)watersheds nor include temporal aspects, as required by ISO 14046 for a proper water footprint and impact assessment. In addition, the differentiation between surface and groundwater and the consideration of unconventional sources such as increasingly used desalinated or reused water remains limited. Furthermore, information on the combination of water sources supplied to a specific user is very scarce, while for background processes the actual origin of water is usually unknown. The aim of this work is to develop a spatially and temporally specific water supply mix for different water user needs. As a starting point, the geographical scope is Europe. The water mix builds on 1) the well established concept of the electricity production mix in Life Cycle Assessment (LCA), 2) specific literature on inclusion of water in the LCI and the Quebec tap water supply mix, already integrated in ecoinvent v3.1. The water mix proposed includes: water origins, water users, spatial and temporal specification and technologies (water abstraction, water production and water distribution). Data collection on water abstraction was done at national and regional (i.e., watersheds) levels per European country. A great spatial variability of water origins for different water users has been observed. There is also a temporal variation throughout the year that should be considered. The water supply mix, a mix of water sources and related technologies to meet a user need at a specific time (season) and location (sub-watershed), provides reliable water use profiles for background (and foreground) systems in LCA and will allow for LCIA methods to distinguish between the trade-offs of the various impact profiles of a given local mix. This project will enable routine assessment of water-use impacts just as straightforward as the use of the electricity supply mix.

Improving the usability of ecotoxicology in regulatory decision-making: findings from a SETAC Pellston® Workshop

48
How to improve the quality of ecotoxicity studies
J.W. Green, DuPont / Applied Statistics Group
This presentation will address how we can go about 'improving the quality and reporting of ecotoxicology studies'. By advancing these two aspects, we should be able to increase the number of studies that can be used in the risk assessment process. Overall, there is consensus around what constitutes a well-conducted ecotoxicity study; and that these factors should be required for publication in the peer-reviewed literature. These include, but are not limited to, confirmed exposures, minimum replication, appropriate controls and control performance, and data transparency and sharing. Implementation of these recommendations by journals, and adoption of these practices by researchers at the study performance level, will facilitate the evaluation of the quality of work by all scientists, and draw more defensible data into the regulatory decision-making.

49
The student perspective
M. Agerstrand, Stockholm University / Environmental Science and Analytical Chemistry

50
Panel discussion
M. Agerstrand, Stockholm University / Environmental Science and Analytical Chemistry
Moderated panel discussion focusing on questions that the panel members get in advance. Panel members: Allen Burton (University of Michigan, USA/editor ET&C), Thomas-Benjamin Seiler (Aachen University, Germany/chair of SETAC Europe Advisory Group on Science and Risk Communication), Natalie Burden (NC3Rs, UK), Henrik Sundberg (Swedish Chemicals Agency, Sweden) Discussion points: 1) Comments on the results from the SETAC Pellston workshop. 2) How can scientific journals enhance and maintain the quality of ecotoxicity studies? 3) Do scientific journals have any responsibility to publish standard guideline studies? 4) What role do the institutions that fund research play? 5) How can SETAC contribute?

51
Questions

52
Evaluating reliability and relevance of ecotoxicity studies
C. Moermond, RIVM / Centre for Safety of Substances and Products
This presentation will address the following questions: What types of problems can be anticipated when evaluating ecotoxicity studies for regulatory risk assessment? What are the appropriate reliability and relevance evaluation criteria for peer-review publications? Can the available evaluation methods be used for regulatory risk assessment? e.g., Klimisch, CRED, EPA Soils (EcoSSLs), or other guidelines for evaluating ecotoxicology data, and methods of other disciplines – toxicology, evidence-based medicine, etc. It also will highlight frameworks that can be used to better design studies so they can be used in the regulatory process and what is needed for these studies to be evaluated for reliability and relevance to risk assessment and risk management.

53
Weight of evidence evaluation
T. Hall, Bayer CropScience / Environmental Toxicology and Risk Assessment
In order for sound risk assessment and risk management decisions to be made, the Weight of Evidence (WoE) procedures must be objective, systematic and transparent. We reviewed the current quantitative and qualitative methods used by regulatory agencies and those found in the general literature. The goal was to develop a method that allow the weighing of the lines of evidence in a prospective risk assessment that then demonstrate the reliability, relevance, adequacy and consistency of the information. The general obstacles and difficulties when performing WoE evaluations in regulatory risk assessment were discussed. Through this evaluation a series of recommendations and approaches have been developed that allow for all scientific evidence relevant to a hypothesis to be considered and evaluates the strengths and value of the ecotoxicology data in the risk assessment.

54
Panel discussion
M. Agerstrand, Stockholm University / Environmental Science and Analytical Chemistry
Moderated panel discussion focusing on questions that the panel members get in advance. Panel members: Anu Kapanen (ECHA, Finland), Jose Tarazona (EFSA, Italy), Jason Snape (AstraZeneca, UK) Discussion points: 1) Comments on the results from the SETAC Pellston workshop. 2) What is needed from researchers to

increase the use of peer-reviewed studies in regulatory risk assessments? 3) What can regulatory agencies and industry do to ensure that all relevant and reliable data is included in dossiers? 4) What are the barriers that exist, and potential solutions, to making industry-sponsored studies more transparent? 5) Future needs? 6) How can SETAC contribute?

55
Questions

Contaminants of Emerging Concern in the Environment and their Management (II)

56
Transformation products found in full-scale wastewater ozonation and biological post-treatment
C. McArdell, Eawag / Department of Environmental Chemistry; M. Boehler, Eawag / Department of Process Engineering; E. Borowska, M. Bourgin, Eawag / Environmental Chemistry; J. Fleiner, Eawag / Process Engineering; J. Hollender, Eawag / Environmental Chemistry; C. Kienle; R. Teichler, Eawag / Environmental Chemistry; H. Siegrist, Eawag / Process Engineering; U. von Gunten, Eawag / Water Resources
In Switzerland, a new water protection act was approved in spring 2014 which asks for the upgrade of around 100 out of 700 wastewater treatment facilities with advanced treatment to eliminate micropollutants within the next twenty years to enhance surface water quality. The WWTP Neugut in Dübendorf is the first facility in Switzerland where ozonation has been installed before sand filtration for the abatement of micropollutants. As the contaminants are not fully mineralized during ozonation, transformation products are produced. The elucidation of these transformation products and their potential adverse effects for the environment is of concern. In the scope of the study was: (i) determination of reactivity of compounds with ozone and identification of ozonation products (OPs) of selected compounds, (ii) investigation of the formation of OPs in the ozonation at the full scale facility in the WWTP Neugut and of their fate in different biological post-treatments, and (iii) investigations of different effects with bioassays in the laboratory and directly on the WWTP in a flow-through systems. In the study pharmaceuticals which occur in significant concentrations in WWTP effluents were investigated in detail. Species-specific second-order rate constants for the reactions of the molecular and dissociated forms of eight compounds with ozone were determined. The investigated compounds were found to represent a wide range of reactivity. For three compounds, different OPs were proposed from measurements with high-resolution mass spectrometry, MS2 spectra analysis and expert knowledge on ozone reaction mechanisms. Several OPs could be confirmed with available standards. N-oxides were quantified with high yields as the primary OPs for tertiary amines. In the bacteria bioluminescence assay performed on ozonated and non-ozonated samples of the three compounds cetirizine, fexofenadine, and hydrochlorothiazide, the toxicity was slightly increased during the ozonation of cetirizine, however, only at cetirizine concentrations higher than what is found in wastewater treatment. The assessments of the ozonation effluent of WWTP Neugut confirmed the results from lab studies concerning reactivity with ozone and the formation of OPs. Several OPs from the literature were also found after ozonation at this plant. The evaluated OPs were mostly stable in the different biological post-treatments investigated after ozonation.

57
BIOMONITORING AND SOURCE TRACKING OF DIOXINS IN THE NETHERLANDS
A. Arkenbout, Toxicowatch Foundation
In the region of Harlingen, situated in the north of the Netherlands, people are becoming very concerned about adverse health effects related to the possible emission of dioxins and other POPs by a waste incinerator installed in 2011. A monitoring programme using backyard chicken eggs, shows a serious pollution with dioxins and dl-PCBs in the environment of Harlingen harbour. In order to find the source of this pollution, the preliminary results of analysis of a long-term sampling of the flue gas of the incinerator will be discussed in relation to the congeners found in the backyard chicken eggs.

58
Fate, metabolism and transformation of wastewater-borne pharmaceuticals and their transformation products in the aquatic environment and fish in European rivers
S. Perez, IDAEA-CSIC / Environmental Chemistry; J. Aceña, M. Hannemann, J. Peña, IDAEA-CSIC; D. Barcelo, IIQAB-CSIC / Dept Environmental Chemistry
The presence of pharmaceuticals residues in the aquatic environment has caused concerns about potential adverse effects on exposed wildlife. Pharmaceuticals prior to entering WWTPs have already been metabolized in humans which leads to biotransformation products with different chemical structures and physico-chemical properties compared to their parent compounds. After their excretion in conjunction with their human metabolites and their discharge into the sewer, they enter in WWTPs where they can be further transformed by secondary treatments and advanced treatments generating transformation products (TPs). Several studies have been reported the occurrence of pharmaceuticals, their human metabolites and their TPs in wastewater treatment plants (WWTPs), surface waters and different fish tissues, but still very little is known about their fate in fish. Fish have been shown to possess hepatic detoxification systems capable of metabolizing xenobiotics taken up from polluted waters. In this context, we propose to screen surface water samples and fish for a large number of TPs formed in WWTPs and rivers. In order to have a broad perspective of the transformation of pharmaceuticals detected in surface waters and their metabolism in freshwater fish a suspect screening of pharmaceuticals, TPs and their predicted metabolites was applied in all samples from around Europe. With this approach several pharmaceuticals and TPs, more than 50 compounds, were detected in surface waters. In fish more than 15 phase I metabolites were detected, corresponding to different hydroxylation reactions, and phase II metabolites such as glucuronide and taurine conjugates were tentatively identified. The suspect analysis of muscle allowed the detection of more than ten different pharmaceuticals. The analysis of fish bile has allowed for the detection of several phase I and phase II metabolites and suggests that the occurrence of drug metabolites in bile can be used as a surrogate for exposure of fish to pharmaceuticals. Currently, the identification of several TPs and metabolites still requires confirmation. In accordance with the literature, anti-inflammatories, antibiotics and psycho-active drugs have been the most commonly detected drugs. Thus this approach highlights that UPLC–HRMS is a powerful tool for simultaneous quantitative and qualitative analysis, allowing the search for suspected compounds, TPs and metabolites, their identification and the quantitation of target compounds.

59
Removal of contaminants of emerging concern (CECs) during primary, secondary and tertiary wastewater treatment steps
Z. Baalbaki; T. Maere, P.A. Vanrolleghem, modelEAU - Université Laval / Département de génie civil et de génie des eaux; V.V. Yargeau, McGill University / Chemical Enineering
Contaminants of emerging concern (CECs), including pharmaceuticals and hormones, are secreted by humans and end up in wastewater treatments plants (WWTPs) that are not designed to treat them, resulting in the occurrence of CECs in water bodies.This study consists of both experimental and modelling work and aims at understanding the removal of 19 target CECs, including hormones, pharmaceuticals and some of their main metabolites, during primary, secondary and tertiary treatment. The WWTP studied is the Guelph WWTP, ON, Canada (120,000 PE). The treatment train consists of primary clarification, activated sludge, rotating biological contactors and sand filtration. Sampling campaigns were carried out on four consecutive days in the summer, where 24-hr composite aqueous and sludge samples were collected. Aqueous and sludge samples were extracted by solid phase extraction and accelerated solvent extraction, respectively, and the extracted samples were analyzed by LC-HRMS. Conductivity was measured throughout the plant and used as a tracer for the calibration of the hydraulic model of the treatment plant that was built using the wastewater simulation software WEST (MikeByDHI.com). The hydraulic model was used to obtain load fractions, which were used along with experimental CECs concentration data to obtain reliable removal levels of CECs. Results showed that for some CECs, such as carbamazepine and codeine, the average mass loading in the effluent was as high as 20 g/d. It was also found that the majority of CECs had low removal rates in the primary clarifier stage and most of their removal took place in the activated sludge unit, with removal rates >70% for some of the target CECs. Concentrations of CECs in primary sludge ranged from 2 to 200 ng/g. The removal of CECs in rotating biological contactors, for which limited data is available in literature, and sand filtration was found to be < 30% for most of the CECs, although a few of them were efficiently removed by sand filtration. The experimental removal rates were used to calibrate a model that predicts the fate of CECs during primary and secondary treatment. This model can be used as a design and optimization tool in WWTPs.

60
First Swiss wastewater treatment plant with full-scale ozonation - Ecotoxicological assessment of ozonation and several post-treatments
C. Kienle; H. Besselink, Biodetection Systems BV; S. Fischer, Eawag, Swiss Federal Institute of Aquatic Science and Technology / Environmental Toxicology; S. Flückiger, Xenometrix AG; B. Ganser, S. Gut, S. Hasler, Swiss Centre for Applied Ecotoxicology Eawag-EPFL; M. Langer, Oekotoxzentrum Eawag-EPFL / Aquatic Ecotoxicology; A. Schifferli, Swiss Centre for Applied Ecotoxicology Eawag-EPFL; S. Santiago, Soluval Santiago; K. Schirmer, Eawag / Environmental Toxicology; L. Schlüter-Vorberg, ECT Oekotoxikologie GmbH; C. Thiemann, R. Triebskorn, University of Tuebingen / Animal Physiological Ecology; B. van der Burg, Biodetection Systems BV; E. Vermeirssen, Oekotoxzentrum Eawag-EPFL / Aquatic Ecotoxicology; M. Weil, ECT Oekotoxikologie GmbH / Institute for Technology Assessment and System

Analysis ITAS; I. Werner, Swiss Centre for Applied Ecotoxicology / Department of Anatomy Physiology and Cell Biology
Emerging pollutants in wastewater, such as pharmaceuticals and personal care products, can be eliminated by advanced wastewater treatment techniques. Thus the discharge of these substances into freshwater ecosystems can be diminished and drinking water resources can be protected. Previous studies have shown ozonation to be a promising technique to eliminate micropollutants, even though it can produce reactive and potentially toxic transformation products. To remove these transformation products, which are often biologically degradable or bind to particles, post-treatments like sand filtration or granulated activated carbon are recommended by the Swiss Federal Office for the Environment (FOEN). The wastewater treatment plant (WWTP) Neugut is the first in Switzerland to apply a full-scale advanced treatment of wastewater with ozone followed by sand filtration. In the present study, the efficiency of ozonation and a number of post treatments to reduce ecotoxicological effects of biologically treated wastewater were assessed using a set of bioassays. Post-treatment methods were: a full-scale sand filtration, pilot-scale granulated activated carbon (GAC), and pilot-scale fixed and turbulent fluidized beds. *In vitro* bioassays were applied in the laboratory and *in vivo* bioassays with living organisms were performed in the laboratory and on site The investigations revealed that the wastewater treatment with ozone resulted in significantly reduced ecotoxicological effects, improved growth and photosynthesis of green algae, decreased toxicity to luminescent bacteria, and decreased estrogenicity, compared to effects measured in the waste water from the secondary clarifier. The post-treatments partially lead to a further decrease of the effects. Only the reproduction of water flea and oligochaetes was not influenced by any of the treated wastewaters compared to unpolluted control water, whereas fish partially showed developmental and histopathological effects after ozonation, which could be reduced with suitable post-treatments. The applied *in vitro* and *in vivo* bioassays showed that biological effects related to effluents can significantly be reduced by ozonation followed by a suitable biological post-treatment such as sand filtration or granulated activated carbon treatment. The study was financed by the FOEN (ReTREAT project) and by the EU in frame of FP7 (DEMEAU project no. 308339).

Electrochemical oxidation of fluoroquinolone antibiotics: Mechanism, residual antibacterial activity and ecotoxicity

L. Zhu, Forschungszentrum Juelich GmbH, ZEA-3 / ZEA; B. Santiago-Schübel, Forschungszentrum Jülich GmbH; H. Xiao, Institute for Environmental Research RWTH Aachen; H. Hollert, RWTH Aachen University / Department of Ecosystem Analysis; S. Küppers, Forschungszentrum Jülich GmbH
Introduction Fluoroquinolone antibiotics have been detected in WWTPs effluents, surface water and various environment matrixes. Continuous release of FQs may induce antibiotic resistance and ecotoxicity to aquatic organisms and humans. Increasing studies have focused on the removal of FQs by Electrochemical advance oxidation processes (EAOPs). However, a comprehensive understanding of oxidation mechanisms of FQs during EAOPs has not been reported before. Furthermore, various intermediates and products of FQs might form during EAOPs and release into the environment. Little attention has been paid to evaluate the environmental effects of electrochemical oxidation effluents which contain oxidation products with potential hazard. The objective of this paper is to comprehensively study electrochemical oxidation mechanisms of ciprofloxacin (CPF), norfloxacin (NOR) and ofloxacin (OFL) and evaluate potential environmental risks of FQs and their oxidation products. **Methods** A commercial flow-through EC cell was respectively connected to a QTRAP 2000 and a high-resolution ESI-FTICR-MS Ultra. Scaling up reactions were conducted in a mg level EC cell. The disk diffusion test indicates antibacterial activity was carried out according to Disk Diffusion Test Methodology by EUCAST with slightly modification. The algal growth inhibition tests with *Desmodesmus subspicatus* were following to OECD 201. The EC_{50} were calculated by software ToxRat Professional XT. **Results** Eight oxidation products were respectively elucidated for each parent compound. Oxidation pathways were proposed on basis of product structraures and transformation trends. Oxidation and ring cleavage of the piperazyl substitute represent the main oxidation mechanisms of FQs by electrochemical oxidation while fluoroquinolone core remained unchanged. CPF, NOR and OFL respectively formed larger inhibition zones than their oxidation product mixtures at all exposure concentrations. The results reveal that the oxidation products of CPF, NOR and OFL collectively exerted weaker activity than their parent compounds after electrochemical oxidation. The EC_{50} values of CPs and NPs are almost the same as that of their parent compounds respectively whereas the EC_{50} value of OPs are much lower than that of OFL after 72h exposure. Our results indicate toxic intermediates were generated during electrochemical oxidation which contributed to the combined toxicity of oxidation mixtures to the green algae.

Flame Retardants: Alternatives, Environmental Fate and Toxicity (I)

62

Legacy and emerging Flame Retardants in the Global Ocean Atmosphere

B. Gonzalez-Gaya, Institute of Environmental Assessment and Water Research / Environmental Chemistry; J. Roscales, Institute of Organic Chemistry of the Spanish National Research Council (IQOG-CSIC); J. Castro-Jimenez, Aix Marseille University, CNRS/INSU, University of Toulon, IRD, Mediterranean Institute of Oceanography (MIO); B. Jimenez, IQOG-CSIC / Instrumental Analysis Environment; J. Dachs, IDAEA-CSIC / Environmental Chemistry
The use of flame retardants (FRs) is a common practice to avoid the flammability of consumer goods like textiles, furniture, foams, electronics and building materials. FRs exhibit environmental persistence and long range transport potential, behaving like persistent organic pollutants (POPs). Due to their global occurrence, bioaccumulation potential and toxicity some legacy FRs are regulated (e.g. poly brominated diphenyl ethers (PBDEs)) and thus, alternative FRs have been launched in the recent years to substitute the banned compounds (e.g. dechlorane plus (DP) and organophosphate esters (OPEs)). This study includes the occurrence of 15 PBDEs, syn- and anti-DP isomers and 2 dechlorinated forms of anti-DP, and 14 OPEs analyzed and quantified in oceanic aerosol. Over 110 air samples were taken during the Malaspina circumnavigation cruise between 2010-2011 which crossed the north and south basins of Atlantic and Pacific oceans as well as the Indian Ocean, between 30ºN and 40ºS covering all the tropical and subtropical oceanic gyres. Moreover, dry deposition fluxes were calculated with a parametrization of the deposition velocities for each FR. This is the first combined assessment of legacy and emerging BFRs, including PBDEs, DPs and OPEs in the oceanic atmosphere, showing the ubiquitous presence of these pollutants even in remote oceanic regions, and the atmospheric load to the open ocean through aerosol dry deposition.

63

Emerging Flame Retardants in Air in the Canadian Great Lakes Basin

H. Hung, Environment Canada / Air Quality Processes Research Section; N. Alexandrou, K. Brice, Environment Canada; C. Shunthirasingham, University of Toronto Scarborough / Departments of Chemistry and Physical and Environmental Sciences; H. Dryfhout-Clark, K. Su, R. Park, R. Noronha, C. Shin, Environment Canada
Persistent organic pollutants (POPs) and other priority organic pollutants are being measured in air in the Canadian Great Lakes Basin (GLB) at land-based stations since 1990, in support of the Canada/US Great Lakes Water Quality Agreement (GLWQA). Air samples were screened for new chemicals of concern, such as emerging flame retardants (FRs), to assess the risks that these pollutants may pose to wildlife and humans in the GLB. In this study, results from atmospheric measurements of emerging brominated (BFRs) and chlorinated (CFRs) flame retardants are reported in comparison with measurements of polybrominated diphenyl ethers (PBDEs). Hexabromobenzene (HBB), allyl 2,4,6-tribromophenyl ether (ATE), 1,3,5-tribromobenzene (TBBz), anti- and syn-dechlorane plus (anti-DP and syn-DP) were dominant FRs found at two GLB sites, namely Point Petre on Lake Ontario and Burnt Island on Lake Huron, with levels mostly lower than PBDEs. Similar to the PBDEs, lighter FRs in air showed a strong sesaonality with higher concentrations in the summer months. Higher FR air concentrations were found at Point Petre, which is closer to urban developments, than at Burnt Island. While air concentrations of PBDEs were declining in Great Lakes air between 2005 and 2013, which may be related to control efforts, no consistent changes in air concentrations were observed for most emerging FRs (2009-2013).

64

Organophosphate Flame Retardants in ambient air of Bursa, Turkey

P.B. Kurt Karakus, Bursa Technical University / Environmental Engineering Department; H.A. Alegria, University of South Florida; A. Birgul, Bursa Technical University; H. Celik, Akdeniz University; E. Gungormus, T. Ugranli, İzmir Institute of Technology
Flame retardants are chemicals that are added to many consumer products such as plastics, electronics, textiles, and foams for furniture, automobile interiors and many others. The most widely used flame retardants are polybrominated diphenyl ethers (PBDEs), although others have been used, including hexabromocyclododecane (HBCD), tetrabromobisphenol-A (TBBP-A), organophosphate flame retardants (OPFRs), decadibromodiphenyl ethane (DBDPE), 1, 2-bis (2,4,6-tribromophenoxy)ethane (BTBPE) and others. Over the recent past, PBDEs have undergone much scrutiny because of their persistence and toxicity. Research interest has started to focus on the non-PBDE flame retardants. Although organophosphate flame retardants (OPFRs) have been widely used for decades, after some studies in the 1980s indicated that these chemicals degrade quickly in the environment no more studies were carried out on them for a long time. More recently, a few studies have indicated that they are persistent and are subject to long-range transport. There is now increased interest in understanding their environmental fate and transport. In Turkey, there are few studies on PBDEs in the environment, in indoor air and dust however, to the best knowledge of the authors there are not any studies on the organophosphate flame retardants in ambient air in Turkey. Levels of flame retardants in indoor air and dust were found to be at ng levels indicating that such chemicals are abundant in Turkish environment. However, detailed surveys were not conducted to investigate such chemicals in Turkey. This highlights the need to understand the

levels, sources, and movement of flame retardants in the Turkish environment. In this study, re report levels of certain OPFRs in ambient of Bursa, Turkey that was obtained during the course of a 1-year passive sampling study.

65

Monitoring levels of legacy and emerging flame retardants in indoor environments: a multi-location study between Norway and the UK

K. Kademoglou, University of Reading / geography and Environmental Sciences; F. Xu, University of Antwerp Toxicological Center / Toxicological Centre Dept of Pharmaceutical Sciences; A. Covaci, University of Antwerp, Toxicological Center / Toxicological Center Dept of Pharmaceutical Sciences; L.S. Haug, Norwegian Institute of Public Health; C.D. Collins, Reading University / Soil Research Centre

Living in the post-PBDE era entails production, commercial use and gradual replacement of fire-inhibiting compounds with newly manufactured chemicals also known as "emerging" halogenated flame retardants, such as EH-TBB & BEH-TEBP (Penta-BDE replacement), BTBPE (Octa-BDE replacement), DBDPE (Deca-BDE replacement), Dechloranes (DPs) (Deca-BDE replacement) or organophosphorus flame retardants (PFRs; TPHP, TCPP etc.). The main objectives of the present study are: a) To assess the occurrence of legacy and emerging alternative FRs across two European countries (the UK and Norway) with respect to human exposure via dust ingestion. No data have been reported yet on emerging PFRs, also known as novel PFRs (NPFRs), in dust from residential or occupational microenvironments neither for the UK nor for Norway. In addition, this is the first study reporting significant levels of NPFRs including isodecyldiphenyl phosphate (iDPP) and trixylenyl phosphate (TXP) in indoor microenvironments. b) To identify possible FR sources with respect to the collection source and country of origin, taking into consideration source variability and its impact on usage of emerging FRs in consumer products. Dust samples (n=22) from vacuum cleaner bags (10 houses and 12 stores, offices, libraries) in the UK were collected during August 2013 – December 2013. Dust samples (n=10) were collected from vacuum cleaner bags (houses) in Norway during November 2013 – April 2014 as a part of the A-TEAM cohort sampling within the framework of the '*Advanced Tools for Exposure Assessment and Biomonitoring'* (A-TEAM) project, a Marie Curie Initial Training Network aiming to establish tools for human exposure biomonitoring of emerging FRs. In the present study, a broad range of legacy and emerging FRs were studied, including PBDEs, novel BFRs, PFRs and novel PFRs. A commericial shift and gradual replacement from the phased-out FRs to emerging FRs is evident. We are the first to identify and report on NPFRs, such as iDPP and TXP in indoor dust originating from residential and occupational environments, suggesting extensive usage of NPFR-coated consumer products in the UK and Norway. This project is financially supported by the European Commission FP7 Marie Curie Initial Training Network "A-TEAM" grant number 316665.

Biomagnification study of hexabromocyclododecane isomers in freshwater fish and invertebrates

M. Lauzent, LPTC-EPOC, University of Bordeaux / UMR EPOC LPTC; P. Labadie, CNRS; S. Augagneur, K. Le Menach, University of Bordeaux / UMR EPOC LPTC; A. Ferrari, PROBIEN, CONICET -UNComahue; M.P. Babut, Irstea / Water; H. Budzinski, University of Bordeaux / UMR EPOC LPTC

Since 2011, hexabromocyclododecane (HBCD) is subject to authorization (Regulation N° 143/2011 EU) and considered as persistent, bioaccumulative and toxic (PBT); this compound is included in Annex A of the Stockholm Convention since 2014, and became a priority substance for water in Europe since 2013 (Directive 2013/39 / EU). As for several other priority substances, the Environmental Quality Standard (EQS) for HBCD is set for biota (i.e. fish), meaning that compliance checking will have to refer to fish. HBCD is an additive brominated flame retardant (BFRs), used especially in the building sector, thermal insulation, textiles, electrical equipment. In this context, the aim of this work was to determine trophic magnification factors (TMF) in various rivers and streams in France, and to examine their spatial-temporal variability. HBCD isomers (α, β and γ) were analysed in fish and benthic invertebrate tissues. These samples were collected from five study sites representing different river conditions (catchment size and anthropogenic pressure). All the concentrations found in fish and invertebrates were below the Environmental Quality Standard EQS_{biota} (167 $ng.g^{-1}$ wet weight (ww)). α-HBCD displayed the highest trophic magnification factor and significant differences were observed between sites. The determination of TMFs by 3 different models (linear regression, censored regression and GLMM) has shown the importance of the regression model used for TMF assessment. It is therefore important to consider the different aspects of data treatment (e.g. heterogeneity in the number of samples), all the while knowing that each model has its limitations.

67

Fishing of unknown halogenated environmental contaminants in environmental sentinel based on isotopic pattern and mass defect through untargeted high resolution mass spectrometry profiling

R. Cariou, Oniris-LABERCA / Oniris Laboratoire dÉtude des Résidus et Contaminants dans les Aliments; A. Léon, E. Omer, LUNAM Université / Oniris Laboratoire dÉtude des Résidus et Contaminants dans les Aliments; G. Dervilly-Pinel, B. Le Bizec, Oniris-LABERCA / Oniris Laboratoire dÉtude des Résidus et Contaminants dans les Aliments

Bioaccumulation of Persistent Organic Pollutants (POPs) is predictably associated with the compounds characterised by high lipid solubility thus an ability to accumulate in the fatty tissues of living organisms for long periods of time. POPs increase in concentration in the food chain and are typically halogenated organic compounds. In the case of known substances, targeted approaches mainly based on mass spectrometry (MS) are available to characterise human exposure (environment, food) as well as body burden (human tissues and fluids). These quantitative methods do not permit however to detect non yet described exposure markers, i.e. degradation products of known substances or unknown/emerging substances. Last generations of high resolution mass spectrometers (HRMS, e.g. orbitrap or TOF) open the way to untargeted full scan footprints as a new methodological approach for addressing this issue. Large datasets arise from such HRMS couplings with chromatography from which the extraction of the useful information stands as a central question, thus requiring the development of fit-for-purpose intelligent data processing, analysis and visualisation tools, supported by appropriate biocomputering solutions. In our work, we discuss the proof of concept of a new methodology capable of seeking unknown organohalogenated compounds in environmental sentinels. Our strategy relies on an automated peak picking step based upon the centWave function (xcms package, R environment), a VBA script developed for pairing features according to the exact mass difference between Cl and Br isotopes to filtering potential organohalogenated clusters among full scan HRMS datasets. H/Cl-scale mass defect plots were used to visualize the datasets before and after filtering. The filtering script was successfully applied to an LC-HRMS untargeted profiling dataset generated from an eel sample muscle extract obtained after pressurised liquid extraction and a non selective liquid-liquid partitioning between concentrated sulphuric acid and hexane. From 9,789 initial features observed in the eel muscle extract, 1,994 features were paired in 589 clusters containing at least an M+2 contribution (indicating a Cl or a Br atom), allowing for realistic manual investigations of filtered clusters. Hexabromocyclododecane, chlorinated paraffin series and other candidates were fished and for some of them identified.

Microplastics in the environment: Sources, Fate and Effects (II)

68

What, when and where? Assessing temporal and spatial trends in microlitter>10μm in coastal waters west of Sweden

T.M. Karlsson; M. Hassellov, University of Gothenburg / Department of Marine Sciences; F. Norén, IVL Swedish Environmental Research Institute

Comparable datasets are a luxury within marine litter research, due to the novelty of the field. These golden glimpses of information provide valuable insights in trends of abundance and characteristics, to understand sources and pathways and can also help us plan sampling and monitoring to achieve and increased accuracy in future comparisons. On the Swedish west coasts measurements of $\text{microlitter}_{>10\mu m}$ have been carried out at 14 locations using comparable methods at 4 occasions during 3 years.In a recently initiated project these datasets are evaluated to achieve a detailed overview of differences in composition and abundance. Preserved samples of commonly found anthropogenic microscopic litter such as blue, red and white particles and fibers are additionally being analyzed using FTIR. Initial comparisons of the datasets show that a consistently higher amount of particles were found on the smaller sized filters (10μm). Interestingly the composition here also differed, with a often higher amount of fibers and black particles on the smaller filters in relation to the classic polyolefin and expanded polystyrene microplastics on the filters with a wider pore size (300μm). The industrial harbor area by Galterön separates from the others on account of the relative high composition of synthetic fibers, red particles and black particles in the range of 50-100 μm. FTIR analysis are being carried out to further investigate these relationships, and to see how they might relate to activities in the area. The city areas of Älvsborgsbron, Skalkorgarna and Danafjord show some separation form the others, which is clearest in the results from 2013. The strongest separation is for Älvsborgsbron which is also the sampling point closest to the urban areas of Gothenburg which fits earlier observationswhere cities hav e been identified as a source of microlitter. The compositional differences here show a high amount of black particles with a probable origin in incineration processes, it also shows a high composition of plastic particles and to some extent also blue particles. The initial results of the ongoing analysis show higher amounts but also clearer trends in composition for the >10 μm samples than for the samples collected with a 300 μm net. It is therefore suggested that sampling and monitoring of smaller size classes of microlitter are important to understand temporal and spatial differences in microlitter abundance and composition.

69

Neustonic microplastics in the Bay of Brest (Brittany, France): composition, abundance and spatial distribution

L. Frère, LEMAR UMR 6539 CNRS; I. Paul-Pont, C. Lambert, LEMAR UMR 6539 CNRS/UBO/IRD/Ifremer; E. Rinnert, Ifremer, Laboratoire Détection, Capteurs et Mesures - Centre de Bretagne; J. Moreau, Ifremer, Laboratoire Détection, Capteurs et Mesures - Centre Bretagne; P. Soudant, LEMAR UMR 6539 CNRS/UBO/IRD/Ifremer; A. Huvet, Ifremer, LEMAR UMR 6539 CNRS/UBO/IRD/Ifremer
Since a decade, microplastics represent an increasing concern for science and society with many studies establishing their fate and their impact in aquatic ecosystems. Many studies have been reported microplastic occurrence throughout the world ocean and in different environmental matrix such as water, sediment and biota. Some of these emergent contaminants can release toxic chemical compounds added during their manufacturing or adsorb from the surrounding seawater, both being possibly released in marine environment and biological matrices. In this context, studies aiming to determine the extent and impact of this pollution for marine ecosystems biodiversity and services are of great interest. In the present study, the abundance, composition and spatial distribution of microplastics were investigated in April 2014 from surfaces water of the Bay of Brest (Brittany, France), which is divided in three zones (north, central and south) characterized by different hydrodynamics and anthropogenic pressures. Microplastics particles were of the following classification: 0.3-1 mm, 1-2 mm and 2-5 mm. A combination of static image analysis of particles and automated Raman micro-spectroscopy was used to obtain the counting, size, shape and chemical composition of a large number of particles for each sample. 35 % of visually sorted particles were not identified as plastic polymer, so morphological criteria such as color, shape or texture are insufficient to assert that a particle is a plastic polymer. Eight of the nine stations contained microplastics particles and a mean concentration value of 0.269 particles / m^3 (i.e. 0.619 mg / m^3) was estimated. Only 65 % of particles collected at surface water were identified as plastic suggesting that visual sorting is not enough. A majority of polyethylene (76 %) was identified. The spatial distribution of microplastics in the Bay of Brest seems to be different between the three zones: the central zone exhibited the highest value (0.540 particles/m^3), followed by the North zone (0.218 particles/m^3), whereas only few microplastics were collected in the south part (0.049 particles/m^3). The south zone was mostly polluted by an important concentration of fibers but analyses are currently ongoing to identify their chemical composition and confirmed their plastic nature.

70

Abundance of microplastics and adhered contaminants in the North Atlantic Ocean

K. Syberg, C.M. Knudsen, Roskilde University / Department of Environmental Social and Spatial Change; Z. Tairova, Aarhus Universitet, Nordre Ringgade 1, 8000 Aarhus C, Denmark; F. Khan, Roskilde University / ENSPAC; Y. Shashoua, The National Museum of Denmark; T. Geertz, H.B. Pedersen, Plastic Change, Henningsens alle 16, 2900 Hellerup, Denmark; C. Sick, Plastic Change; T.B. Knudsen, Roskilde University / Department of Environmental Social and Spatial Change; J.H. Jørgensen, NIRAS A/S, Sortemosevej 19, 3450 Allerød, Denmark; A. Palmqvist, Roskilde University / Department of Environmental Social and Spatial Change
Marine plastic contamination has increased steadily over the last decades, and plastic debris account for more than 90% of the marine litter encountered by marine wildlife. The majority of the plastic litter can be characterized as microplastic (MP). Those plastic types that have a density below that of seawater will float on the sea surface for a prolonged period of time, and will therefore be transported with currents. This has led to a concentration of plastic debris in oceanic gyres. One of the five major oceanic gyres is situated in the North Atlantic Ocean and elevated concentrations of MPs have been reported in this area. Apart from direct physical effects such as clogging of gills and entanglement, plastic may also serve as a vector for other lipophilic contaminants, which can bind to and be transported with the plastic. The importance of such vector effects are not fully understood and are currently being discussed in the scientific literature. The current study reports findings and analyses of microplastic samples along a transect from the Caribbean Sea into the North Atlantic Gyre conducted in spring 2015. The aim was to: i) quantify abundance of MP ii), estimate relationships between size and distribution of MPs, iii) determine concentrations of lipophilic contaminants adhered to the MPs and iv) generate a GIS based map where data are included, that subsequently can be expanded to include data from other surveys and thus help inform decision makers about the marine plastic pollution. The studies showed that MPs dominated by PE and PP are abundant in surface waters of the North Atlantic Gyre and that smaller fractions were more dominant then larger. The analyses further documented that PCBs and PAHs can bind to the MPs at concentrations higher than those observed on biosamples. This illustrates that MPs can be important as vector for other contaminants. GIS mapping is a very useful communication tool that can be used to inform the public and policy makers, and thus facilitate measures to prevent future pollution. The GIS map is a useful tool for updating the data and displaying them for the scientific community as well as the public and policy makers. It may therefore be an effective tool in the work towards promoting mitigation measures.

71

Microplastics in the Rhine-Main area in Germany: Occurrence, spatial distribution and sorption of organic contaminants

S. Klein, Department of Chemistry and Biology; E. Worch, Technische Universitaet Dresden / Institute of Water Chemistry; T.P. Knepper, Hochschule Fresenius, University of Applied Sciences
Synthetic polymers are one of the most significant pollutants in the aquatic environment. Serious effects are expected from so-called microplastics (particle size The sediment was sampled from the river Rhine, the river Main and the stream Schwarzbach. Sampling was done by a randomized sampling approach. Small sediments samples along the shoreline of the rivers were taken and combined to batch samples for each sampling site. Using a modified density separation with subsequent sample clean-up and Fourier transform infrared spectroscopy or microscopy (FTIR), microplastics were separated from river shore sediments, resulting in large amounts of microplastic particles of up to 1 g kg^{-1} or up to 4000 plastic particles kg^{-1}. The identification by FTIR showed that polyethylene, polypropylene and polystyrene were the most abundant polymer types in the sediments, covering over 75% of all plastics identified. Furthermore, a possible transport of microplastics from tributaries to main streams was indicated by the detection of identical pellets at sampling sites in the River Rhine and in the Main mouth. Microplastic concentrations did not correlate with the population density of the sampling area. One sampling site was monitored over two years in intervals of five to nine months. Comparable concentrations were detected in the sediment and suggest a constant pollution of the river shore sediments with microplastics. Additionally, large microplastics (>500 μm) were extracted using ultrasonic-assisted extraction or extraction by dissolution and subsequent size exclusion chromatography. The extracts were analyzed by GC/MS and LC-MS/MS using target screening methods and non-target approaches. Different pesticides or polycyclic aromatic hydrocarbons were identified in the polymer particles, suggesting that microplastics can act as a sink for hydrophobic contaminants. Moreover, several plastic additives such as phthalates or chlorinated flame retardants were identified. For this reason, it is very likely that microplastics act as a direct source for these chemicals in aquatic systems. The results of this study stress the urgency for the mitigation of the plastic particles in the aquatic environment.

72

Microplastics in inland waterways and coastal waters - origin, fate, and impact

N. Brennholt, Federal Institute of Hydrology / Biochemistry Ecotoxicology; C. Scherer, Goethe University Frankfurt am Main / Aquatic Ecotoxicology; M. Wagner, Goethe University Frankfurt / Aquatic Ecotoxicology; F. Schmitt, J. Girardi, C. Kochleus, Federal Institute of Hydrology; A. Weber, Goethe University Frankfurt am Main / Aquatic Ecotoxicology; S. Hatzky, Federal Institute of Hydrology; G. Reifferscheid, Federal Institute of Hydrology / Department Biochemistry and Ecotoxicology
The accumulation of plastic debris in aquatic environments is one of the major but least studied human pressures on aquatic ecosystems. Under environmental conditions, larger plastic items degrade into smaller particles, so-called microplastics (MP) (< 5 mm in diameter). MP resulting from degradation processes are classified as secondary MP, while primary MP are produced as such for industrial purposes. MP particles represent freshwater contaminants of emerging concern. However, to assess the environmental risks associated with MP particles in freshwater ecosystems, comprehensive data on their abundance, fate, sources, and biological effects are needed. Therefore the research project "Microplastics in inland waterways and coastal waters – origin, fate, impact" by the Federal Institute of Hydrology (BfG) aims at establishing scientific principles for assessment, monitoring and regulation of MP in freshwater aquatic environments (water and sediment). Within this project the following tasks will be addressed: (1) occurrence (quality and quantity) of MP in inland waterways, (2) characterization of quantitative and qualitative input in waterways and coastal waters (mass balance study), (3) bioaccumulation potential of MP, (4) investigation of biological effects of MP on aquatic organisms, and (5) risk assessment for aquatic organisms and aquatic environments. On this account the research project consists of 5 work packages: (I) sample preparation and qualitative description, (II) development and validation of quantification methods, (III) biological effects, (IV) modeling and monitoring, and (V) leaching, impact, and risk assessment; of these the first results will be presented here.

73

Microplastics in various compartments of the urban water cycle

R. Dris, ParisEst University; j. gasperi, LEESU / LEESU laboratoire eaux environnement et systèmes urbains; V. Rocher, SIAAP; B. Tassin, Leesu - Enpc / LEESU laboratoire eaux environnement et systèmes urbains
If the occurrence of microplastics, particles smaller than 5 mm, in both marine and continental environments have been studied, their inputs are still very poorly identified and only few works focused on their sources. This work aims at assessing the microplastic contamination in different compartments of the urban water cycle. Greywater and wastewater were first studied. Washing machine effluents have been collected in the houses of four volunteers. Three consecutive washes were considered, the first one with an empty washing machine, the second

one with the washing product only, and the last one as a regular wash. Microplastics in WWTP influents and effluents were also analyzed during 3 campaigns. Conventionnal 24-hour averaged samples were collected. Atmospheric fallout and rainwater were collected in two different sites, one urban (1 year) and one sub-urban (a half year), through a collection funnel. Stormwater samples were collected at the outlet of a small sub-urban catchment during six rain events. The two first samples of washing machine effluents (empty machine and without clothes) contained between 120 and 150 particles/L. When clothes are washed, concentrations between 8850 and 18700 particles/L were encountered, confirming the large contribution of the clothes. High levels of fibrous plastics are found in WWTP influents (260 – 320 particles/L) while the concentrations in the effluents are in the 14 – 50 particles/L range. A microplastic removal rate between 83 and 95% have been estimated. Throughout the year of monitoring (urban site), an average atmospheric fallout of 110 ± 96 particles/m^2/day (mean ± SD) was encountered. On the suburban site, a 6-month monitoring shows an atmospheric fallout around 53 ± 38 particles/m^2/day. Through all the monitoring period, a significant difference between the atmospheric fallout on the urban and the sub-urban site was found. By considering the rainwater volume collected on the atmospheric fallout funnel, a median concentration of 40 particles/L can be estimated. In runoff, the first results indicated that the microplastic concentrations lies in the same order of magnitude, i.e. between 39 and 60 particles/L range. To date, further work is required to evaluate the contribution of total atmospheric fallout to stormwater pollution.

Fate, Effects and Risk Assessment of Chemicals in Aquatic and Terrestrial plants (II)

74

Ecosystem services approach to pesticide risk assessment and management of non-target terrestrial plants: recommendations from 2 SETAC Europe workshops

G. Arts, Alterra Wageningen University and Research Centre / Environmental Risk Assessment; L. Maltby, The University of Sheffield / Dpt of Animal Plant Sciences; M. Dollinger, Bayer CropScience AG / Environmental Safety Ecotoxicology; E. Kohlschmid, Agroscope / Institute for Plant Production Sciences IPS; C. Mayer, BASF SE / Ecotoxicology; G. Meregalli, Dow AgroSciences Italia srl / Environmental Regulatory Sciences Ecotoxicology; H. Ochoa-Acuna, DuPont Crop Protection / Environmental Safety and Ecotoxicology; V. Poulsen, ANSES / French Agency for Food Environmental and Occupational Health and Safety; F. Streissl, EFSA / Pesticides Unit

The registration of Plant Protection Products (PPPs) in the EU falls under Regulation 1107/2009, which recommends a tiered approach to assessing the risk to non-target terrestrial plants (NTTPs). However, little information is provided on how to perform and implement higher tier studies or how to use them to refine the risk assessments. Therefore, two workshops (April 2014, Sept 2015) were organized with the aim of: developing a framework for a higher-tier approach to assessing the risk of PPPs to NTTPs; providing expert opinion and advice as input for the ongoing revision of the terrestrial ecotoxicology guidance document and NTTP risk assessment procedures. The recommendations agreed to by the first workshop relate to the three main themes, i.e. specific protection goals, risk assessment and mitigation. The participants of the workshop adopted the European Food Safety Authority (EFSA) approach of using an ecosystem services framework for identifying specific protection goals. First, delivery and protection of ecosystem services were discussed for in-crop, in-field *and* off-crop, and off-field areas. Second, lower and higher tier risk assessment methods, including modelling approaches, were evaluated and the benefits from these options were addressed. Third, options for risk mitigation of spray drift and run-off were discussed and evaluated. A number of concerns were raised during the workshop and literature reviews were performed and data collected in order to reduce uncertainty. These actions focussed on the protectiveness of standard test species for wild species; the protectiveness of regulatory endpoints for reproductive endpoints; the methods and endpoints for multispecies or field-studies; and the importance of different exposure routes for non-target terrestrial plants. The second workshop built upon the results of these literature reviews, the recommendations of the first workshop and the EFSA opinion on risk assessment of PPPs for NTTPs. The main charge questions identified for the second workshop were: how to address reproductive endpoints; how to mitigate risks; how to conduct higher tier tests. A higher-tier framework for NTTP risk assessment was proposed. Recommendations from both workshops will be presented.

75

Sensitivity of NTTPs to plant protection products - vegetative and reproductive endpoints: Literature review and analysis for SETAC AG Plants

H. Christl, Tier3 Solutions GmbH; M. Dollinger, Bayer CropScience AG / Environmental Safety Ecotoxicology; C. Mayer, BASF SE / Ecotoxicology; G. Weyman, ADAMA Agricultural Solutions Ltd.; J.P. Wright, Monsanto Company / Ecotox and Env Risk Assmt; S. Loutseti, DuPont De Nemour Hellas S.A.; G. Meregalli, Dow AgroSciences Italia srl / Environmental Regulatory Sciences Ecotoxicology

A literature review was performed comparing vegetative and reproductive endpoints for non-target terrestrial plants (NTTPs) aiming to test the hypothesis that reproductive endpoints are more sensitive than the standard vegetative endpoints currently used to inform the pesticide risk assessment. In addition the EFSA Scientific Opinion [1] was considered, in which, among others, also reproductive endpoints were discussed to be more sensitive than the currently assessed vegetative endpoints. The dataset listed in [1] was assessed in parallel to the full data set (that also included confidential industry data). In addition current proposals to move from ER50 to ER10 endpoints were investigated. Although cases are reported of reproductive endpoints considerably lower than vegetative endpoints, based on the data assessed here the difference between the two was found to be minor, on average just a factor of ca. 1.5. Even if both endpoints (vegetative and reproductive) were always determined and the lowest of the two was used in the RA, the average gain in protectiveness would just be a factor of ca. 2 (based on the EFSA dataset). In contrast, the difference between ER50 and ER10 was greater than a factor of 6. A change of the effect level used in the RA (ER50 to ER10) would thus increase the conservatism of the tier1 RA for NTTPs considerably. The ecological relevance of a 10% reduction at the population and landscape level, advantages and disadvantages of the proposed change in effect level, a potential alternative by using the ER25 (or ER50 with an additional assessment factor), and if there is a need for an increase in conservatism of the tier1 risk assessment will be discussed.

76

What information can we gain by including trait-based endpoints for plants in ecotoxicological tests? Case studies with Myriophyllum spicatum, the new OECD test organism for rooted aquatic plants

E.M. Gross, University of Lorraine / Laboratoire Interdisciplinaire des Ecosystemes Continentaux; A. Nuttens, Universite de Lorraine / Laboratoire Interdisciplinaire des Environnements Continentaux LIEC UMR CNRS; F. Tabane, Universite de Lorraine; A. Hussner, Heinrich-Heine University Düsseldorf

In plant ecology, the trait concept provides functional markers for plant functions. Plant functional traits (morphological, physiological, phenological) reflect ecological strategies and determine how plants respond to environmental factors. Trait variability can reflect adaptations or acclimations at the intraspecific level. We hypothesize that morphological and physiological traits change in the presence of certain pollutants. Leaf, stem and root mass fractions (LMF, SMF, RMF), dry matter content (DMC) and stoichiometry, the content in carbon, nitrogen and phosphorus and resulting C:N:P molar ratios in plant tissue are traits that can provide information about effects at the individual level or allow extrapolations on ecological interactions and ecosystem processes. We tested our hypotheses exposing sediment-grown *Myriophyllum spicatum*, the new OECD test species to arsenic or mixed herbicide. Experiment 1 had a cross-factorial design with two CO_2-levels (low and high, LC and HC) and four arsenate levels. Experiment 2 exposed plants to isoproturon (IPU) or mesosulfuron-methyl (MSM) alone or in varying combinations. After two weeks, we measured final plant length, fresh and dry weight and dissected a part of the shoots into leaves, stems and roots, and determined C, N, and P contents. In experiment 1, arsenate and/or CO_2 availability affected morphological and physiological plant traits. SMF increased in arsenic-exposed plants, and was higher in the HC treatments. RMF declined to one third at high arsenic levels. LMF was affected both by CO_2 availability and arsenic levels. Arsenic level affected the DMC of leaves, stems and roots, but only roots exhibited a lower RDMC under LC treatments. Arsenic affected the N and P content and resulting C:N and C:P ratios in the whole plant, while CO_2 availability affected C content and CP and NP ratios. In contrast, we observed very little effects on C, N and P content in leaves. In experiment 2, IPU alone had no effect on LMF, but with increasing proportion of MSM, the LMF declined strongly. At the same time, SMF increased strongly with increasing MSM. With increasing MSM, the LDMC increased strongly compared to solvent controls or IPU. We conclude that incorporating different plant traits as endpoints with *M. spicatum* can provide valuable information useful to predict ecological effects of pollutants. Our experiments have shown that such changes in plant traits are frequent.

77

Demonstration of Reciprocity of Effects of four Sulfonyureas on Myriphyllum spicatum

H. Ochoa-Acuna, DuPont Crop Protection / Environmental Safety and Ecotoxicology; A. Kirkwood, Smithers Viscient / Ecotoxicology; T. Scown, DuPont Crop Protection; J.R. Hoberg, Smithers Viscient / Ecotoxicology; C.R. Picard, Smithers Viscient / Sediment and Plant Ecotoxicology

The dependence of toxicity on not only the dose, but also time was first described by Haber. Haber's law states that the incidence and/or severity of a toxic effect depends on the toxic load i.e., the exposure concentration times the duration of exposure. For toxicants that block an enzyme's activity, the effect will depend on the number of bound molecules *per unit time*. Sulfonylureas have been known to follow this pattern of action. These herbicides act by inhibiting the ALS enzyme

responsible for producing branched amino acids. Given that growth is a time-rated process, large growth inhibitions exerted during short periods are comparable to lower inhibition over more prolonged periods. In this series of studies, we demonstrated that the inhibitory action of four sulfonyureas on the aquatic macrophyte *Myriophyllum spicatum* follows Haber's law. Two distinct exposure regimes (1- and 3-days), but at reciprocal exposure levels were run, meaning that exposures expressed on a TWA basis were the same. During each variable duration test, three termination intervals were conducted, at 3, 7 and 14 days. At each interval, a set of replicates was terminated and biological data collected. The response of *Myriophyllum spicatum* to these sulfonylureas clearly follows Haber's law, in that the effects resulting from different exposure levels, but of reciprocal duration, were not statistically different. Either 1- or 3-day exposures of *Myriophyllum spicatum* to the four SUs resulted in similar growth rate values for shoot length, and wet and dry shoot weights measured at either 3, 7, and 14 days after the beginning of exposures. There is previous data on metsulfuron methyl showing that EC_{50} values *Lemna minor* exposed for 42-d of continuous exposure were not similar to those calculated for 4- and 2-d, but reciprocal (TWA) exposures. Also, a study with metsulfuron methyl on *Myriophyllum spicatum* showed the same result when comparing the same 21-d TWA, but with different peak exposure concentrations and exposure periods (1, 3, 7, 14 or 21d). The data presented here further validate the conclusion by EFSA in relation to the validity of a TWA for methsulfuron methyl and also agrees with data collected for the better-studied *Lemna* spp. These results allow to recommend that the reciprocity assumption, and therefore allowance for the use of a 7-day TWA concentration, should be considered as a standard refinement for the risk evaluation of sulfonyurea herbicides.

78
Effects of pulsed mixtures and recovery in Lemna minor based on POCIS field measurements.
S. Marley, CRP Henri Tudor / Environmental Research and Innovation ERIN; R. Carafa, LIST / ERIN; H. Cauchie, Luxembourg Institute of Science and Technology LIST / Environmental Research and Innovation ERIN; R. Altenburger, UFC Centre for Environmental Research / Bioanalytical Ecotoxicology
Pesticide contamination, in particular herbicidal loading, has been shown to negatively affect Luxembourgish river quality. Such pressure can have direct impacts on autotrophic species, and wider indirect impacts on the freshwater community through the degradation of primary production. The EC report on the toxicity and assessment of chemical mixtures indicated a method to determine the best approach for the evaluation of pesticide mixtures in the environment. However it is difficult to incorporate the variety and combination of compounds sold, used, and detected in surface waters into bioassays. Literature regarding pesticide mixture toxicity shows the validity of the 'concentration addition' (CA) concept for mixtures of compounds with similar modes of action, and the 'independent action' (IA) concept for mixtures of dissimilarly acting compounds. However a mismatch exists between real field exposure patterns and typical laboratory tests. This study attempts to bridge this gap by directly using spiked mixtures of pertinent compounds based on whole field extracts. Mixtures were applied in pulsed scenarios determined from passive sampling campaign results, in order to determine the toxicity of these real environmental mixtures to a representative autotroph. High risk compounds were selected based on sales, use, and historical detection data, in combination with toxicity values and compound characteristics. Herbicidal loading was determined using passive samplers (POCIS) over eight months, spanning two years and twelve representative streams in Luxembourg. LCMS analysis of these samples indicated the time-weighted average herbicide load over the exposure period. Seven day bioassays using the floating macrophyte *Lemna minor* were then performed to determine the toxicity of six high risk compounds and spiked artificial mixture based on whole field extracts. Bioassays were performed in pulsed scenarios mimicking exposures determined from POCIS results. Early results indicate metazachlor to be the most toxic of the selected compounds (EC_{50} 0.0106 mgL^{-1}). Further tests will clarify the toxicity of these compounds in mixtures and pulsed scenarios to the floating macrophyte *Lemna minor*. Presented here are the results from: (i) *L. minor* bioassays using both whole spiked mixture, and pulsed mixture scenarios (ii) use of CA and IA concepts to fit *L. minor* pulsed and spiked mixturebioassay results.

79
Pesticide mixture toxicity to algae in agricultural streams - field and laboratory studies
W. Goedkoop, Swedish University of Agri Sciences / Department of Aquatic Sciences and Assessment; J. Rydh Stenström, Swedish University of Agricultural Sciences / Department of Aquatic Sciences and Assessment; J. Kreuger, Swedish University of Agricultural Science / Centre for Chemical Pesticides
Contamination of surface waters with multiple chemical pesticides is well documented, but little is known about their concerted effects on aquatic communities. We collected water samples from four streams in small agricultural catchments in southern Sweden during a whole year. In addition to pesticide analyses, we used these water samples to run algal growth inhibition bioassays with *Pseudokirchneriella subcapitata*. In addition, we identified worst-case samples observed in long-term monitoring of pesticide water concentrations (> 80 pesticides) and used these to run tests with reconstituted pesticide mixtures in algal growth medium to specifically test their combined effects on algal growth. Both for bioassays with *in situ* water samples and mixture toxicity tests we used controls that consisted of standard growth medium. *In situ* water samples were spiked with nutrients to rule out confounding effects of nutrients. Long-term monitoring data showed more than 10 pesticides in 63% or more of the 902 collected water samples, with 90-percentiles ranging 21–29. The average number of pesticides in a single sample ranged 9-18, while the maximum was 41. These results stress the complexity of exposure by pesticides in agricultural streams. However, despite the multitude of pesticides in a sample, toxicity was frequently set by one or a few dominating compounds that contribute to more than 90% of the mixture's toxicity. $\sum TU_{algae}$ for long-term monitoring data exceeded 0.1 on 28 occasions, 70% of which occurred between May and July, i.e. the period when spraying is most intensive. Bioassays with *in situ* water samples showed a significant inhibition of algal growth in 49% of the 61 samples that were run during a whole year. On four occasions algae grew better in *in situ* water than in controls. There was no relationship between growth inhibition and estimates of pesticide toxicity (i.e. PTI and ΣTU_{algae}), suggesting that also chemical stressors other than pesticides could have contributed to the observed inhibitions. Tests with reconstituted medium showed that significant inhibition of algal growth occurred in the range of 1–10x the $\sum TU_{algae}$ observed in monitoring data. For all mixtures but two, calculated EC_{50}-values were between 3 and almost 10-fold higher than literature values for the dominant pesticide. The calculated EC_{50}-values for most of the mixtures were 2–17 times higher than those estimated by the model of concentration addition.

Metals in the Environment: Fate, Speciation and Bioavailability in Water, Soil and Sediment (II)

80
Investigating fractionation and speciation of metal(loid)s in sediment pore water samples
A. Fabricius, Federal Institute of Hydrology / G aquatic chemistry; L. Duester, D. Ecker, T. Ternes, German Federal Institute of Hydrology BfG
In aquatic environments the fate and behaviour of inorganic and organic substances is often driven by biogeochemical gradients at the sediment water interface (SWI), like gradients of e.g., the oxygen concentration, the redox potential or the pH value. Important transport processes at the SWI are sedimentation and resuspension of particulate matter and diffusional fluxes of dissolved materials. Beside this, the speciation of elements at the SWI is important to asses relevant reactions as well as potential effects. To investigate the factors and processes that govern the distribution and fluxes of nutrients, metals and metalloids (metal(loid)s) at the SWI, the analytes of interest in the sediment pore water have to be studied in parallel to different sediment parameters. Several methods for an active (e.g., suction, squeezing or centrifugation), or a passive (e.g., dialysis or DGE/DET) pore water sampling are available. These often require the installation of the sampling devices at the sampling site and/or intensive preparation procedures (e.g., slicing and centrifugation or re-elution from/digestion of the accumulation gels), probably impacting the environmental conditions at the area studied and/or the characteristics of the samples taken. The authors developed suction based, direct and low invasive sampling methodologies that enable to study element distributions in sediment pore water at the SWI at different spatial resolutions (sub-mm to cm) and depths (2 cm – 20 cm within the sediment). By combination of this micro or meso sampling system with a mircroprofiling system (Missy/Messy) and different sample preparation procedures, it was possible to address the fractionation (size dependent and micelle mediated) as well as the speciation of metal(loid)s in parallel to different sediment parameters (O_2, redox and pH) along sediment depth profiles. The profiling experiments were complemented by slurry reactor experiments enabling to simulate specific conditions by controlling the redox potential. The vision of the experimental approaches is to address a variety of parameters in parallel and, thereby, to help to deliver a more holistic understanding of natural and anthropogenic caused processes that govern the fate of substances at the SWI. Within the presentation, the results of different Missy and Messy experiments will be given. The different approaches will be discussed, especially with regard to their potentials and limitations and in comparison to other methods.

81
Chromium speciation and release from mining waste in Barro Alto and Crominía, Goias state, Brazil
S.V. Bolanos Benitez, Institut de Physique du Globe de Paris, Sorbonne Paris Cité, Univ. Paris Diderot; Y. Sivry, IPGP - VAT FR79197534282; J. Garnier, UnB, IG/GMP-ICC Centro, Campus Universitario Darcy Ribeiro; C. Quantin, UMR 8148 GEOPS, Université Paris Sud - CNRS; M. Tharaud, Institut de Physique du Globe de Paris, Sorbonne Paris Cité, Univ. Paris Diderot; P. Lens, UNESCO-IHE Institute for Water Education; E. Hullebusch, Université Paris-Est, Laboratoire Géomatériaux et Environnement
Chromium is abundant and naturally present in ultramafic rocks and serpentine

soils. However, anthropogenic activities such as mining, leather tanning, chrome plating and metallurgical industries release an important amount of chromium into the environment. In spite of existing in chemical forms displaying oxidation number from 0 to VI, only hexavalent (Cr(VI)) and trivalent chromium (Cr(III)) are stable enough to occur in the environment. Despite Cr(III) is not toxic and more stable under natural conditions, Cr(VI) is known to be highly soluble in water, bioavailable and toxic. In plants the toxicity of Cr(VI) results in the suppression of seed germination, chlorosis of its leaves and oxidative stress (Choppala et al., 2013). In human and animals, the dermal contact is the most important exposure pathway, and as a result Cr(VI) easily crosses physiological barriers, enters into the blood stream, and destroys the red corpuscles (Jacobs and Testa, 2005). In order to determine the potential release of Chromium from mining activities and its impact on the environment, chemical extraction, chemical leaching under controlled physico-chemical conditions and isotopic exchange techniques associated with mineralogical studies has been applied in solid samples (soils, ores and sediments) collected in two areas located in Goiás State (Brazil). The first site is Barro Alto, Ni mining and metallurgic area, and the second is the Crominía, old chromite exploitation area. The chemical exchangeable Cr(III) and Cr(VI) were extracted with KCl 1M and KH_2PO_4 0,1 M respectively. Controlled leaching experiments were carried out with a $NaNO_3$ 10^{-3} M and NaN_3 0.02% leaching solution (S/L ratio of 20:1), controlling Eh and monitoring other parameters (pH, DO, Fe, Anions, etc). In addition, isotopic exchange was performed with ^{50}Cr (4.35% of abundance). The samples obtained from the chemical extraction and the isotopic exchange were all analyzed with HR-ICP-MS (ThermoScientific Element-II). Additionally, X-ray diffraction (XRD) analyses were performed on soils powder and shown that the mineralogy of the ores and soils was dominated by iron oxides. X-ray fluorescence (XRF) and acid digestion with Inductively coupled plasma atomic emission spectroscopy (ICP-AES) analysis were used to assess the total element concentrations of the solid samples. The results of the chemical extraction and ionic chromatography indicates that exchangeable Cr is mainly under hexavalent form.

82

Do climate conditions affect metal bioaccumulation in earthworms?

M. González-Alcaraz, Faculty of Earth and Life Sciences, VU University / Ecological Science; K. van Gestel, VU University Amsterdam / Ecological Science

The present study aimed to assess the effects of changing climate conditions (temperature and soil moisture content) on the bioaccumulation of Zn and Cd in the earthworm *Eisenia andrei* in soils polluted by metal mining wastes. Bioassays were performed in different metal-polluted soils (mine tailing and watercourse) and under different combinations of temperature (20 and 25 °C) and soil moisture content (50 and 30% of the soil water holding capacity - WHC). Adult earthworms were individually exposed to the study soils for 21 days and analysed for internal Zn and Cd concentrations at different times. Before and after 21 days of exposure soils were analysed for pH and metal concentrations in porewater. The mine tailing soil did not show changes in metal availability (Zn-1, Cd-1). In the watercourse soil, porewater concentrations of Zn and Cd significantly decreased after 21 days exposure to the different climate conditions tested (Zn: from ~3761 to ~1613-2170 $\mu g\ L^{-1}$; Cd: from ~63 to 32-41 $\mu g\ L^{-1}$), especially at 20 °C and 50% of the soil WHC (standard conditions). In the latter soil, metal availability decrease was accompanied by a significant pH increase at 20 °C and 50% of the soil WHC. Both study soils showed a similar Zn bioaccumulation pattern in earthworms, without differences among climate conditions. Earthworms reached the highest internal Zn concentration after 1 day of exposure (~450-1500 $\mu g\ g^{-1}$ d.w.) then remaining constant until the end (typical pattern of essential elements). The Cd bioaccumulation pattern changed when changing the climate conditions. At 20 °C and 50% of the soil WHC the internal Cd concentration continuously increased from ~4 to ~13-19 $\mu g\ g^{-1}$ d.w. (typical pattern of non-essential elements). But when increasing temperature and/or decreasing soil moisture content the pattern changed towards a pattern typical of essential elements due to increased Cd elimination rates (mine tailing: from ~0.11 to 0.24-1.27 d^{-1}; watercourse: from ~0.07 to 0.11-0.35 d^{-1}) and faster achievement of a steady state. This study shows that soil incubation for 21 days under controlled conditions decreased Zn and Cd availability in metal-polluted soils, with higher decreases at 20 °C and 50% of the soil WHC. Changing climate conditions modified the bioaccumulation pattern of Cd in *E. andrei* exposed to metal-polluted soils, with faster achievement of the steady state due to higher elimination rates.

83

Keeping memory of past mining activities: assessment of trace metal bioavailability and ecological risk using active biomonitoring.

A. Mariet, UMR 6249 Chrono-environnement; B. Pauget, University of Franche-Comte, UMR UFC/CNRS 6249; A. de Vaufleury, University of Franche-Comte / Department of ChronoEnvironment; C. Bégeot, A. Walter-Simonnet, University of Bourgogne Franche-Comté, UMR UFC/CNRS 6249; F. Gimbert, University of Franche-Comte / UMR ChronoEnvironnement

Mining activities are the first substantial source of trace metals (TM) contamination of the whole environment. However, past mining activities are often forgotten or minimized due to the disappearance of visual marks while mining wastes are known to be highly concentrated in TM. Bioavailability of TM and risk assessment linked to past mining and smelting activities are developed in a past mining district in the Vosges Mountains (France) to reconstruct their environmental impact in a forested valley. A bioindication campaign using the land snail *Cantareus aspersus* as bioindicator of TM bioavailability was conducted for six weeks along a gradient of soil TM concentration with eight stations comprising two archaeological mining stations, a communal garden, four forested stations and a control station. Three microcosms were placed in each station with fifteen snails per microcosm. Each week, two snails were randomly sampled for digestive gland TM analyses. Bioavailability of TM is evaluated by the uptake rate of TM. Bioavailability of TM is high in the eight stations compared to recent industrial sites, highlighting the importance of knowledge of localization of past mining and smelting sites. Moreover, the two archaeological mining sites present the highest bioavailability of TM to snails with, for example, 68.40 $\mu g_{Pb}.g_{dg}^{-1}$dry weight.d^{-1} and 0.027 $\mu g_{Cd}.g_{dg}^{-1}$dry weight.d^{-1}. A high bioavailability of TM is observed in the communal garden. These results conduct to assess the risk of this past contamination by using two indicators, i.e. SET and ERITME index which allow assessing the excess of transfer and the toxicological risk linked to TM. Excess of transfer and toxicological risks linked to archaeological mining sites are the highest ever measured with these index. Those calculated for the communal garden are similar to those on recent industrial sites. In conclusion, this study highlights that time elapse since the deposit of contaminated particles from mining and smelting activities is not sufficient enough to strongly catch TM in soils without transfer to trophic chain.

Water quality assessment of a catchment affected by historical lead mining

M. Valencia, R. Slack, University of Leeds / School of Geography; A. Stockdale, University of Leeds / Graduate School of Earth and Environmental Sciences; R. Mortimer, Nottingham Trent University / School of AnimalRural and Environmental Sciences

Historical metal ore extraction and processing have resulted in severe water quality issues worldwide. In England and Wales approximately 20% of water bodies fail the objectives of the Water Framework Directive (WFD). Environmental agencies from the United Kingdom and the European Union are constantly challenged in the implementation of this directive, therefore applied research and monitoring programmes are essential for the understanding of metal ion speciation, mobility, accumulation and bioavailability in river ecosystems. In northern England an exhaustive study has been carried out in an upland catchment polluted by heavy metals from historical mining. This research aims to identify the sources of pollution in the catchment and overall significance to water quality criteria for better management and potentially remediation of surface and ground water. A multi-methodological approach has been applied including water quality monitoring and conventional chemical analyses (Ion chromatography, ICPMS) for determining metal sources and concentrations. Correlation tests and principal component analysis have provided a consistent physicochemical characterization of the catchment, reflecting different sources of minerals that affect its water quality. Results suggest that the major geochemical signals are determined by the contribution of carbonate host rock (Ca^{2+}-Mg^{2+}:DIC:EC r=0.9, p< 0.001), other metals are possibly associated with weathering (Fe^{3+}- Al^{3+} -Pb^{2+}-Cu^{2+}:DOC r=0.2-0.7, p< 0.001) and erosion of mined ores such as sphalerite (ZnS) and galena (PbS)(Zn^{2+}-Cd^{2+}:$SO4^{2-}$ r=0.6-0.7, p< 0.001). Maximum concentrations of Zn^{2+}, Pb^{2+} Cd^{2+}, and Cu^{2+} (7438.4 mg/l, 439.9 mg/l, 47 mg/l, 19.8 mg/l) exceeded the Environmental Quality Standards by 99x, 61x, 313x and 2x, respectively. In addition, the identification of different flow regimes emphasizes their impact on metal discharge. Accordingly, mine channels are considered as important point sources, but a major problem is caused by extensive mine tailings during high flow scenarios becoming significant sources of diffuse metal pollution. Results suggest that a catchment-scale assessment combined with analytical approaches offer reliable information about factors controlling metal inputs (point and diffuse), providing monitoring programmes with a practical way to evaluate heavy metal pollution in headwater catchments.

A field-based approach to linking biological responses of freshwater organisms to sediment contamination by metals

J.I. Jones, QMUL / School of Biological and Chemical Sciences; J.F. Murphy, Queen Mary University of London / School of Biological and Chemical Sciences; A.L. Collins, Rothamsted Research, North Wyke; K. Spencer, Queen Mary University of London / School of Geography; P. Rainbow, The Natural History Museum / Dept of Zoology; A. Moorhouse, the Coal Authority; V. Aguilera, DEFRA; P. Edwards, Southern Illinois University Carbondale / Zoolog; F. Parsonage, DEFRA; H. Potter, Environment Agency; P. Whitehouse, Environment Agency / Evidence

The legacy of contaminated sediment is a serious impediment to rivers meeting the water quality targets set out by the EU Water Framework Directive. Whilst controlled ecotoxicity studies in the laboratory can provide an indication of the sensitivity of biota to sediments contaminated with metals, it can be difficult to relate this to the response of organisms in the field. Under field conditions, a variety of factors can influence the uptake of contaminants, such as metals, from the sediment by biota. These influences can be difficult to accommodate when deriving environmental limits that are relevant to field conditions. Here we have used a GIS approach based on river reaches to match biological data, from Water Framework Directive monitoring programmes of diatoms, invertebrates, fish and macrophytes, to a synoptic survey of riverbed sediment chemistry. A total of 2833 sites were identified with matching sediment and biological data. A threshold biological response to sediment metal concentrations was expected, where the metal would have no influence until a threshold concentration had been exceeded. By modelling the 95%ile, biological response thresholds to sediment concentrations of the metals silver, cadmium, chromium, copper, nickel, mercury, lead, tin and zinc, and the metalloids arsenic and antimony were determined. Based on field data describing the response of the relevant BQEs, the rank order of sensitivity to sediment contaminated with metals and metalloids (from most sensitive to least sensitive) was diatoms < invertebrates < fish < macrophytes. Despite the uncertainty involved in the data matching exercise used to produce the datasets, these findings, based on field data, suggest that for some metals the existing sediment quality guidelines may be too precautionary.

Toxicity Testing in Sediments - Bioassays As Link Between Chemistry and Complex Benthic Community Testing for Sediment Quality Assessment

86

Can transcriptomic biomarkers worthwile enhance sediment-contact tests by molecular biomarkers?

A. Brinke, German Federal Institute of Hydrology; G. Reifferscheid, Federal Institute of Hydrology / Department Biochemistry and Ecotoxicology; R. Klein, Trier University; U. Feiler, Federal Institute of Hydrology; S. Buchinger, Federal Institute of Hydrology / Department G Biochemistry Ecotoxicology

In sediment-contact tests effects caused by sediment-bound pollutants usually are assessed on a macroscopic scale. In this approach a sediment-contact test with rice is enhanced by molecular biomarkers for arsenite contamination. As macroscopic endpoint the inhibition of root elongation was assessed. A dose-response curve for the inhibition of root elongation was characterized and the EC_{50} was calculated as 13 $mg{\cdot}kg^{-1}{}_{dw}$. Molecular endpoints in form of transcript biomarkers were derived from microarray analysis. For this purpose, rice plants were exposed to two arsenite concentrations, namely 11 $mg{\cdot}kg^{-1}{}_{dw}$ and 15 $mg{\cdot}kg^{-1}{}_{dw}$ on spiked artificial sediments. Differentially expressed genes that are dose-dependently induced were selected as candidate biomarkers. From these genes a subset of five genes was analyzed by means of qPCR in rice roots that were exposed to a broader range of arsenite concentrations resulting in gene-specific dose-response-relationships. The five candidate biomarker genes were also characterized after exposure of rice to natural sediments with arsenic concentrations ranging from 13 to 23 $mg{\cdot}kg^{-1}{}_{dw.}$ On arsenite spiked artificial sediments, all genes showed a dose-dependent increase of expression up to a maximum at 9 or 13 $mg{\cdot}kg^{-1}{}_{dw}$ respectively. While on artificial sediments a distinct inhibition of root elongation was observed, on natural sediments only at the highest concentration of arsenic, an inhibiton of root elongation occurred. This finding from the natural sediments contradicted the expectations based on the results of the artificial sediment where an inhibition of the root elongation was observed at lower concentrations. This might be explained by the observation, that rice roots grown on silty natural sediments like, grow thinner, but longer compared to roots grown on sandy artificial sediments. However, one of the selected molecular biomarkers reacted clearly to the contaminated sediment. These findings might suggest that the macroscopic endpoint root elongation is less sensitive on silty natural sediments compared to molecular endpoints, if sandy references sediment is used. In sum, it was possible to identify candidate biomarker genes for arsenite stress by means of an omic-approach. On artificial, but especially on natural sediments, the biomarker react more sensitive than the inhibition of root elongation and thus indicated a stress response before adverse effects become manifest on a macroscopic level.

87

Evaluation and selection of test methods for the assessment of contaminated sediments in the Baltic Sea - The CONTEST project

K.K. Lehtonen, A. Ahvo, Finnish Environment Institute / Marine Research Centre; N. Berezina, Russian Academy of Sciences / Zoological Institute; M. Breitholtz, B. Eklund, Stockholm University / Department of Environmental Science and Analytical Chemistry; K. Jørgensen, Finnish Environment Institute / Marine Research Centre; M. Linde, Stockholm University / Department of Environmental Science and Analytical Chemistry; E. Schultz, Finnish Environment Institute / Laboratory Centre; J. Strand, Aarhus University / Department of Bioscience; K. Ström, B. Sundelin, Stockholm University / Department of Environmental Science and Analytical Chemistry

There is a growing need to establish reliable, scientifically-based assessment methods to assess and classify the degree of contamination in sediments. This is necessary for decision-making concerning regulatory actions towards the reducing of pollution from different sources, removal and re-location of contaminated materials, and on-site remediation measures and the follow-up of these. The purpose of the CONTEST project ("Evaluation and selection of test methods for assessment of contaminated sediments in the Baltic Sea", 2014-15), funded by the Nordic Council of Ministers and the Finnish Ministry of the Environment, was to test, evaluate and select suitable biological methods for the quantitative and qualitative assessment of toxicity of anthropogenically contaminated sediments in the Baltic Sea marine environment. In the project, a battery of biotests currently in use in toxicity assessments were applied using a heavily contaminated harbour sediment as the test matrix. Chemical analysis of the sediment confirmed the presence of high concentrations of polycyclic aromatic hydrocarbons, organotins and trace metals. For the toxicity testing, a series of dilutions was prepared by adding reference sediment to the contaminated one, according to the toxicity results obtained from a preliminary toxicity test using amphipods. Various biological endpoints were examined in different test species, most of them ecologically relevant for the Baltic Sea. The following biotests/endpoints using whole sediments or sediment elutriates were applied: amphipod survival, larval development and biomarkers; gastropod survival, embryo development and imposex; copepod survival and larval development rate; water fleasurvival; sediment avoidance (amphipods); bacterial luminescence; micro- and macroalgae growth inhibition; SOS/umu genotoxicity. The majority of the tests applied showed concentration-dependent negative effects on the test organisms. Ranking of the biotests for recommendation purposes was based on the sum scores of a set of carefully formulated individual assessment criteria applied for each test/endpoint.

88

Bioassays in framework of a triad assessment method for brackish sediments

K. De Schamphelaere; L. Bervoets, J. Teuchies, University of Antwerp / Systemic Physiological and Ecotoxicological Research   Department of Biology; T. Ysebaert, IMARES - Wageningen University / Institute for Marine Resources and Ecosystem Studies; P. Meire, University of Antwerp / Ecosystem Management Depertement of Biology; R. Blust, University of Antwerp / Systemic Physiological and Ecotoxicological Research   Department of Biology

In sediment risk assessment, analysis of the pollutant concentrations is essential in determining the degree and nature of sediment contamination. However, chemical analyses provide no evidence of biological effects as, for example, mixture effects are not accounted for. Bioassays provide valuable information on the toxic effects of sediments, but are carried out under lab conditions and are limited to the testing of a few organisms. An evaluation of the benthic community structure can provide evidence of effects in situ. The sediment quality triad method incorporates measures of various chemical parameters, toxicological effects and benthic community structure in view of conducting an integrated assessment of sediment quality. In framework of developing a triad assessment method for the quality evaluation of brackish sediments, 28 sediment samples were taken along the Scheldt estuary (Sea Scheldt (Flanders) and Western Scheldt (the Netherlands)) and other brackish aquatic systems in Flanders. For these samples, chemical variables (e.g. metals and organic pollutants), toxicological effects and benthic community structure are being assessed. In this study, two sediment contact bioassays and a pore water bioassay are carried out to test their suitability for uptake in a quality triad method for brackish sediments as indicator of ecotoxicological effects. A 28-day sediment contact bioassay with the polychaete worm *Hediste diversicolor* is performed on a selection of the samples, with growth and mortality being evaluated. A 10-day sediment contact bioassay with the amphipod *Corophium volutator* and a 24h pore water test with the rotifer *Brachionus plicatilis*, evaluating mortality, are carried out on all the samples. For the sediments already evaluated mortalities vary between 0%-20% for *H. diversicolor*, between 1%-20% for *C. volutator* and between 10%-43% for *B. plicatilis*. Chemical concentration data are evaluated and compared with existing Sediment Quality Guidelines to assess the expected potential of sediment pollutant concentrations to influence sediment toxicity, and compared with the bioassay results. Through multivariate analysis the chemical, ecotoxicological and biological sediment measures are being analysed to assess the correspondence among the three components.

89

(Dis)Agreement between different Lines of Evidence (LoEs) in the risk-based approach of dredged sediments

J. Larreta, Azti-Tecnalia / Marine Research Unit; M. Belzunce-Segarra, Azti-Tecnalia / Marine Research Division; J. Franco, Azti-Tecnalia / Marine Research Unit; J. Garmendia, I. Menchaca, I. Zorita, Azti-Tecnalia / Marine Research Division

The importance of sediments for the assessment of the quality status of aquatic environments has been thoroughly recognized and sediments monitoring is included in many programmes for the assessment of the quality status of marine environments worlwide. In addition, the assessment of the risk associated to contaminants present in the sediments plays a key role in the management of human activities in coastal areas, particularly dredging and relocation of sediments in ports. The results obtained from studies carried out for the management of dredging activities, in addition to those obtained from monitoring programmes that include sediments, represent a good opportunity to study relationships between different lines of evidence (LoEs) to assess the ecological risk of sediment-bound contaminants In this work we study the relationships between the sediment chemistry, the toxicity testing and the status of biological communities, in order to a) assess the degree of (dis)agreement among these three LoEs; b) identify the factors and conditions more likely distorting the expected cause-effect relationships; and c) suggest improvements in the risk-based approach for the management of dredging operations in the coastal areas of Spain. Data from several studies carried out by AZTI in the Basque coast (N. Spain) for different institutions were considered in this work. Overall, almost 300 sediment samples collected along the Basque coast with chemical information of contaminants (heavy metals and organic contaminants) and, at least, one biological LoE (toxicity testing and/or benthic communities) were considered. Most of the metal concentrations in the sediments were well above the ERL, and values above ERM were frequent, suggesting that adverse toxic effects were likely to occur. Statistically significant correlations have been found between variables of the three LoEs: e.g. %organic matter, PCBs, Cr, Ni and Zn are correlated with AMBI, Microtox® and anphipods toxicity. The quality status of the benthic communities was not clearly related to the others LoEs. This indicates the complex relationships between the chemical and the biological compartments.

90

A weight of evidence approach for assessing remediation of contaminated sediments using food web tissue contamination, biotic condition and DNA damage.

J.M. Lazorchak, U.S. EPA / Office of Research and Development; J. Meier, NCOAA Retired; K. Fritz, M. Mills, U.S. EPA; P. Wernsing, U.S. EPA Office of Research and Development; H. Haring, The McConnell Group; D. Walters, USGS / Fort Collins Science Center; J.M. Kraus, U.S. Geological Survey; B.M. Armstrong, Michigan State University / Fisheries and Wildlife

The Ottawa River drains northwestern Ohio, flowing into Lake Erie's western basin at the city of Toledo. The Ottawa River is a component of the Maumee River Area of Concern (AOC) as defined by the International Joint Commission's Great Lakes Water Quality Agreement. A sediment remediation project took place in the lower 14.2 km of the river where urban and industrial activities impacted the river as a beneficial resource. Sediment was removed based on a surface weighted average concentration model where PCB and PAH levels exceeded targeted levels. This presentation will focus on three biological tools used to assess remedy effectiveness: change in fish, invertebrate and Tetragnathid spider tissue concentrations of PCBs and PAHs, DNA damage in Brown Bullhead and macroinvertebrate biotic condition as measured by Ohio EPA Lacustrine Index of Community Integrity (LICI). From 2009-2013 and again in 2015, pre- and post-remedy sampling of fishes representative of different trophic levels was conducted via electroshocking and fyke net sampling. The study area was divided into three river reaches with distinct hydrogeomorphology. Fish collected from each reach included: Largemouth Bass, Brown Bullhead, White Sucker, Pumpkinseed, Gizzard Shad, Bluntnose Minnow and Emerald Shiner. Blood samples were collected from 10 Brown Bullheads from each reach to assess DNA damage using Comet Assay methods. Multi-plate samplers were deployed for collection of macroinvertebrates for tissue analyses and biotic condition assessment. DNA damage in Brown Bullhead increased during dredging then declined in subsequent years. Largemouth Bass, White Sucker, Brown Bullhead, Pumpkinseed, Bluntnose Minnow, macroinvertebrate & spider tissue concentrations showed no change 3-y post dredging compared to pre-dredging. Gizzard Shad and Emerald Shiner showed lower tissue concentrations 3-y post dredging compared to pre-dredging across the entire project area. No difference in the LICI was found based on samples collected before and after dredging. Based on modeling performed during the design phase, it was anticipated that the long-term clean up goals would be met approximately 10 years after the completion of dredging activities, by 2020.

91

A comparative approach using ecotoxicological methods from single-species bioassays to model ecosystems

A. Hägerbäumer, Bielefeld University / Animal Ecology; S. Höss, Ecossa; E. Claus, Federal Institute of Hydrology / Department Biochemistry and Ecotoxicology; P. Heininger, Federal Institute of Hydrology / Division Qualitative Hydrology; W. Traunspurger, University of Bielefeld / Department of Animal Ecology

Effects on natural nematode assemblages to chemical stress (Zn) were assessed in this study in complex sediment microcosms, including indirect food-web effects, and in acute community toxicity tests, considering direct toxicity only. Responses of the various freshwater nematode species in both approaches were compared to effects of Zn on the well-established model organism *C. elegans* in standardized toxicity tests (ISO 10872). The acute tests were performed with a concentration of 20 mg Zn/L, resulting in a sensitivity ranking of *in situ* nematode species. The findings only partly reflected classifications of nematode species according to the NemaSPEAR[%]-index but underlined the function of *C. elegans* representing the sensitivity of freshwater nematodes. The sediment in the microcosms was spiked with nominal Zn concentrations of 10 and 100 mg Zn/kg Sediment (dw). Over the course of the study, Zn had strong dose-dependent effect on nematode abundance, species richness, and species composition, as well as on the NemaSPEAR[%]-index,with significantly lower values in HD-microcosms. Additionally, standardized *C. elegans*-toxicity tests with whole sediment samples and filtered pore water were conducted to estimate bioavailability and direct toxicity, indicating that concentrations causing sublethal effects in *C. elegans* have already severe effects on natural nematode communities. Even at relatively low pore water concentrations of 1 mg Zn/L, corresponding a 20% inhibition of reproduction of *C. elegans* only, striking effects on the natural nematode assemblages could be observed. By this study, a better interpretation of toxicity bioassays in terms of sediment quality assessment was aimed. Whereas the function of *C. elegans* as representative of nematodes could be confirmed when comparing its sensitivity to common freshwater species, results of the more complex microcosm approaches underline the importance of considering also indirect (food-web) effects. Combining sophisticated experimental tools with field observations allows for more accurate decision making in environmental risk assessment. Data on chemical concentrations, single-species and community toxicity, and in-situ assemblages can be integrated as single lines of evidence in a weight-of-evidence approach. As suitable ecotoxicological tools and ecological indices (NemaSPEAR[%]-index) for nematodes are already available, this organismal group should be used more often in sediment quality assessments.

Advances in exposure modelling: bridging the gap between research and application (II)

92

Exposure to Chemicals in Consumer Products: The Role of the Near-Field Environment

P. Fantke, Technical University of Denmark / Quantitative Sustainability Assessment Division; A. Ernstoff, Quantitative Sustainability Assessment; S. Csiszar, 2Oak Ridge Institute of Science and Education at U.S. EPA; L. Huang, University of Michigan / Dept of Environmental Health Sciences; O. Jolliet, University of Michigan

Humans can be exposed to chemicals in consumer products during product use and environmental releases with inhalation, ingestion, and dermal uptake as typical exposure routes. Nevertheless, chemical exposure modeling has traditionally focused on the far-field with near-field indoor models only recently gaining attention. Further, models that are mostly emissions-based, may not necessarily be applicable to all types of chemical release from consumer products. To address this gap, we (1) define a framework to simultaneously account for exposure to chemicals in the near- and far-field, (2) determine chemical product concentrations for various functional use categories, (3) introduce a quantitative metric linking exposure to chemical mass in products, the Product Intake Fraction (PiF), and (4) demonstrate our framework for various consumer product categories. This framework lends itself to high-throughput calculations for characterizing exposure to the vast consumer product chemical space. The chemical mass in products is used as a starting point for quantifying human exposure obtained by multiplying the chemical concentration (e.g. % w/w) in the product with the amount of product used per defined application. Chemical concentrations in products can be obtained from empirical studies, formulations and associations described in databases, or when unavailable, estimated based on chemical-product functions or regulatory frame formulations. Exposure is quantified by estimating the PiF, the fraction of the chemical in a product that is taken in by humans via each exposure pathway, considering specific compartments of entry into the near-field environment (releases of chemicals encapsulated in articles, indoor air spray, etc.). To estimate PiFs, we combined far-field environmental compartments with near-field compartments and exposure pathways in a multimedia matrix of transfer fractions, with columns and rows for each compartment and exposure pathway. The multiple transfers and PiFs (e.g. from chemicals encapsulated in articles to inhalation of indoor air and dermal uptake via skin contact) were obtained by inverting the transfer fractions matrix, yielding cumulative multimedia transfer fractions. PiFs for various chemicals in products were found to be on the order of $1x10^{-7}$ for semi-volatile organic compounds (SVOCs) in thick flooring, $5x10^{-3}$ for VOCs in indoor air spray, and up to 95% or even higher for ingredients in leave-on cosmetic products.

93

Junge relationships in modelled and measured concentrations of chemical pollutants in the Danube River

C. Coll Mora, Stockholm University / Environmental Sciences and Analytical Chemistry; C. Lindim, Stockholm University / Department of Environmental Science and Analytical Chemistry ACES; M. MacLeod, ITM - Stockhom University / Department of Environmental Science and Analytical Chemistry ACES; A. Sobek, Stockholm University / Department of Environmental Science and Analytical Chemistry ACES

Persistence is an undesirable property of chemicals that is difficult to measure in the real environment. Junge relationships describe the correlation between the relative standard deviation of concentrations of chemicals and their residence times. Once calibrated for a set of compounds they can potentially be used to estimate the persistence of pollutants. The parameter *b* in the Junge equation is a measure of the strength of the relationship between variability in concentrations and residence time.[1] In this study we explored Junge relationships relating the concentrations of chemical pollutants to their degradation half-lives in the Danube River. Concentrations of four hypothetical chemicals with biodegradation half-lives of 7, 15, 30 and 90 days were obtained using the STREAM-EU model [2]. Junge relationships were calculated as 1) "Temporal" relationships from variability during the year at each of the stations, and 2) "Spatial" relationships from variability between the stations on each day of the year. Next, a Junge relationship was calculated from the data of the 2nd Joint Danube Survey (JSD)[3] for caffeine and six pharmaceuticals: benzafibrate, carbamazepine, diclofenac, gemfibrozil, ibuprofen and sulfamethoxazole. Half-lives of the compounds were gathered from literature. We found Junge relationships in the Danube in both modelled and measured concentrations. Results from STREAM-EU show clear Junge relationships for the 4 theoretical chemicals. The parameter *b* ranges between 0.1 and 0.8 for the temporal analysis and from 0.1 to 0.4 for the spatial analysis. The higher *b* values in the temporal analysis are found downstream (i.e. Romania), were population and emissions are relatively low. For the spatial analysis, the higher *b* are found in the month of November. The analysis of pharmaceuticals and caffeine data from the JSD, also shows a Junge relationship with *b* of 0.25, well within the values obtained in the modelled spatial Junge relationships. Modelling results suggest that Junge relationships are more likely to be found during November and downstream in the Danube, but this has not been confirmed with monitoring data. Measurements within the optimal spatial and temporal conditions defined by the modeling analysis could potentially be used to estimate the persistence of other chemical pollutants. [1]MacLeod, et.al. 2013. Chemosphere 93:830-834[2]Lindim, et.al. 2016. Chemosphere 144:803-810[3]ICPDR. 2007. http://www.icpdr.org/wq-db/home

Application of a spatial model to contextualise monitoring data for risk assessment of down-the-drain chemicals over large scales

J. Kilgallon, A. Franco, O. Price, Unilever / Safety and Environmental Assurance Centre SEAC

Regulatory screening level exposure assessments (e.g. EUSES) are based on simple conceptual scenarios at various scales. However, exposure, and therefore risks associated with chemicals, are characterised by high spatial variability. The Scenario assembly tool (ScenAT) is a global screening level exposure model to enable spatially explicit predictions of environmental concentrations of home and personal care chemicals. It uses a simple equation to predict local scale freshwater concentrations (PECs) of chemicals discharged via wastewater, as described in the EU TGD. Calculations are performed for 28,080 spatial units across 88 countries worldwide using GIS data layers for the underlying socio-economic (population, GDP) and environmental parameters (per capita water use, STP connectivity, dilution factor). Using a probabilistic approach, we incorporate sources of uncertainty in input data (tonnage estimation, removal in sewage treatment plants and seasonal variability in dilution factors) into spatially explicit model simulations for two test chemicals: the antimicrobial triclosan (TCS) and the anionic surfactant linear alkylbenzene sulphonate (LAS). We then compare model estimates of wastewater and environmental concentrations of TCS and LAS to monitored data available for the UK. This comparison showed that screening-level modeled probabilistic PECs were higher than mean measured data for TCS and LAS by a factor 3.4 and 1.4, respectively. Considering the uncertainty associated with both model and monitoring data, results suggest that the use of a probabilistic approach using the ScenAT model for screening assessment over large scales is a valid approach, produces output that is consistent with monitoring data, and thereby represents a robust screening level exposure assessment tool. The combination of modelled and monitoring data enables the contextualisation of available monitoring data, focussed on few specific catchments, over larger scales. Such information can be used to support the refinement of exposure assessments as well as for the identification of areas of high concentration for use in higher tier assessments.

95

Exposure hotpots and source apportionment analysis of home and personal care products chemicals in Asia

C. Wannaz, The Unversity of Michigan, Ann Arbor / SPHEHS; A. Franco, J. Kilgallon, Unilever / Safety and Environmental Assurance Centre SEAC; O. Jolliet, University of Michigan

The increasing use of household and personal care (e.g. HPC) products in developing countries requires new tools to assess the potential ecological impacts of HPCs, accounting for local hydrological and use characteristics. This paper therefore aims a) to develop a tiered set of models to describe the hydrological and multimedia fate of releases associated with the use of HPCs in Asia b) to combine the fate model with georeferenced emission scenarios to predict chemical concentrations and to identify of (sub)catchments hotspots, and c) to perform an apportionment analysis to understand dominant near and distanced sources. Geo-referenced emissions scenarios are first determined for the entire region using the ScenAT model and focusing on six different test substances. These emission scenarios are then used as input to the regionalized USEtox (tier 1) and to the Pangea fate and exposure model (tier 2) that has the ability to create scenario-specific multi-scale grids. A more detailed analysis is carried out on the Yangtze and Huai River catchments in China, comparing estimated exposure hotspots with water quality grades. LAS estimated concentrations in freshwater are the highest among the considered HPC chemicals but few LAS monitoring data are available for Asia. The higher resolution of tier 2 leads to higher spatial variation in water concentrations. Of special interest is the contrast between short and long lived chemicals in surface water. For a short-lived substances such as LAS (half-life of 0.29 d), dilution leads to decreasing concentrations in the Yangtze River as we move downstream, whereas concentrations are relatively constant for a less degradable substance. The highest concentrations are observed for the Ying River, a tributary of the Huai River, classified with the poorest grade (V+) for macro indicators of water quality in China. For LAS only a few adjacent cells substantially contribute to the concentration in the terminal cell, 63% of the concentration being due to direct emissions in this terminal cell. In contrast, for triclosan, only 1% of the concentration in the terminal cell is due to direct emissions, 5% from neigbouring Shangai, and the remaining 94% coming from more than 220 cells spread over 2000 km upstream in the catchment. The combination of ScenAT with the multi-scale multimedia model Pangea provides a parsimonious way to identify hotspots and to study them with refined resolution.

96

Countrywide risk assessment concerning the exposure of watercourses to spray drift in fruit growing in the Netherlands

H. Holterman; J. Van de Zande, Wageningen University and Research Centre / Agrosystems Research; H. Massop, Wageningen University and Research Centre / Alterra; J. Boesten, Alterra / ERA team; J. Huijsmans, Wageningen University and Research Centre / Agrosystems Research; M. Wenneker, Wageningen University and Research Centre / Applied Plant Research

For aquatic organisms, the risk of exposure to pesticides depends highly on deposits of spray drift onto surface waters. Downwind off-target deposits of spray drift have been investigated for many years. In fruit crops, pesticide sprays are applied in an upward or sideways direction. Consequently, downwind deposits are significantly higher than those for field crops, where sprays are applied in downward direction. For field crops, various spray drift models have been described in literature. For fruit crops no models are available to assess the exposure of surface waters to spray drift. Recently, a generic spray drift model for pesticide applications in pome fruit crops has been developed based on a large set of experimental data. The model is implemented in an exposure assessment model to estimate pesticide concentrations in all edge-of-field watercourses next to fruit orchards in the Netherlands. The exposure assessment model accounts for a large number of spatially and temporally varying conditions. These include the topography of orchards and their orientation, the spatial distributions of edge-of-field watercourses and their geometry, spatio-temporal frequency distributions of weather conditions (typically, wind speed, wind direction and ambient temperature). Another important factor is the growth stage of the trees at the days of pesticide application. Drift reducing application techniques and multiple spray applications during the growing season are accounted for. All of these features result in an exposure assessment model with a high level of realism. In an extensive simulation study the predicted environmental concentrations (PECs) in the watercourses were computed for all possible spatial configurations. A spatio-temporal statistical analysis on these simulations resulted in a quantitative risk assessment for a representative set of spray application schemes. Currently, the present model is combined with a model describing the fate of pesticides in edge-of-field watercourses. In this way, a realistic simulation study on the fate of pesticides in surface waters can be performed to quantify exposure risk levels for aquatic organisms. This serves higher-tier assessment studies for the authorization of plant protection products.

Risk Assessment of Biocides - latest developments

97

Introductory talk: Overview on the environmental risk assessment for biocides and latest developments of guidance and guidance-related documents

H. Schimmelpfennig, ECHA-European Chemicals Agency / D Biocides

SETAC session: Risk Assessment of Biocides- latest developments, under main track: Risk assessment, mitigation and monitoring **Short abstract Introductory talk: Overview on the environmental risk assessment for biocides and latest developments of guidance and guidance-related documents** Heike Schimmelpfennig, Eugenia Nogueiro, Anna Wik, Simon Gutierrez Alonso ECHA, Annankatu 18, FI-00121 Helsinki, FINLAND **Key words**: environmental risk assessment, biocides, guidance development The aim of the introductory talk is to set the scene on how environmental risk assessment is defined for biocides, on how it is currently performed, where to find relevant guidance documents as well as to provide an overview on current ongoing guidance developments. According to Annex VI of the BPR, any risks arising from the use of a biocidal product needs to be identified, therefore a risk assessment is carried out for the different product types (PTs) to determine the acceptability of the claimed use or otherwise of any risks that are identified. Detailed information on how to perform an environmental risk assessment for biocides is provided on the ECHA webpage. The development of guidance and or guidance-related documents like the ESDs is still ongoing. The following guidance documents have been finalised since entry into operation of the BPR (09/2013): Mesocosm guidance (available as Appendix in Vol. IV Part B) Cut off criteria for groundwater assessment of biocides Volume IV Part B: Guidance on Environmental Risk Assessment – Active Substance Scenario for the biocidal use and emissions from oil platforms PT11/ PT12 for PEC calculation Direct emissions to surface waters in PT 6, 7, 8, 9 and 10 Use scenarios for PT 9 roof membranes Supplement to the ESD for PT 13 Emission Scenario Document for PT 19 PT 21: Fish net scenario in aquaculture The preparation of the following guidance documents is currently coordinated by ECHA, member states are actively involved in the preparations: PT 8: Acceptability of the current methods to assess the exposure/risk of wood preservatives Proposals for standard scenarios and parameter setting of the FOCUS groundwater scenarios when used in biocide exposure assessments Leaching to groundwater from paint, coatings and plaster Harmonisation of leaching tests for PT 7, 9 and 10 - test methods.

98
Mixture toxicity assessment of biocides: Experimental verification of the relevance of additives in wood preservative products
P. Vollmar, J. Heim, ECT Oekotoxikologie GmbH; A. Kehrer, Federal Environment Agency / IV Biocides; F. Sacher, DVGW-Technologiezentrum Wasser; A. Coors, ECT Oekotoxicologie GmbH
The Biocidal Product Regulation requests to consider combined effects of active substances and of active substances and relevant additives in the environmental risk assessment. The present study aimed to inform guidance development regarding the identification of additives as being relevant for such a mixture risk assessment. Furthermore it aimed to verify if theoretical mixture assessments can substitute for ecotoxicological testing of biocidal products or their residues released into the environment. The hypothesis of the study is that the consideration of the active substances and additives of environmental concern is sufficient to reliably predict the aquatic toxicity of biocidal products using the concept of Concentration Addition (CA). \nSeven wood preservative products were chosen for the experimental verification of the hypothesis using green algae (growth rate after 72 h), *Daphnia magna* (immobilisation after 48 h) and fish embryos (mortality after 48 h and/or 96 h). To determine how relevant various types of additives are for a protective mixture risk assessment, the Model Deviation Ratio (MDR) was calculated for different subsets of product components.\nIn general, the CA prediction was (over)protective for the so far tested products. If this can be confirmed as a general finding, the theoretical risk assessment of products by the CA concept appears sufficiently protective to be used as a substitute for product testing, taking only additives into account that are identified as environmentally relevant. The presentation aims to give an overview of the results of all seven tested products and will also discuss whether such findings can be generalized for the risk assessment of biocidal products in view of the limited variability of wood preservative products available for testing in the present study.

99
Biocidal use of anticoagulant rodenticides results in the secondary exposure of non-target animals
S. Koivisto, Finnish Safety and Chemicals Agency Tukes
Residues of anticoagulant rodenticides (AR) in non-target animals were studied in Finland. ARs are transferred to non-target animals when they prey on poisoned rodents. In particular, second generation ARs (SGARs) have been found in non-target animals in many countries. This study focused on species which feed either on rodents or their carcasses and in which ARs have been found in other countries. The animals were either found dead or were shot or trapped for other purposes. Bromadiolone, difenacoum, brodifacoum, flocoumafen and coumatetralyl were analysed in 136 liver samples by an HPLC-triple quadrupole mass spectrometric method. One or more ARs were detected in 87% of samples. ARs were commonly found in eagle owls, tawny owls, raccoon dogs, foxes and mustelids. The most commonly found AR was bromadiolone which was also found in the highest concentrations. Bromadiolone was the most frequently used AR in Finland in 2014. The second most common AR present in the livers was coumatetralyl followed by difenacoum, brodifacoum and flocoumafen. Overall, the prevalence of ARs in non-target species correlated well with the sales of these substances. A high variation of concentrations was found within and between animals. In general, coumatetralyl was found in lower concentrations compared to SGARs. Our results show that the biocidal use causes frequent exposure of non-target animals, because ARs are authorized only as biocides in Finland and the use for the crop protection can be considered negligible. There are several restrictions on the use of ARs in Finland. The most restricted use is allowed to the general public while the professional pest control operators (PCO) have the widest selection of substances as well as a possibility to use ARs outdoors. Even the most restricted substances, i.e. those allowed only to indoor use by PCOs were found, but in lower frequency compared to more commonly used substances. Coumatetralyl was found surprisingly often despite of its anticipated low use and fast elimination half-life. On the other hand, concentrations of coumatetralyl in the baits were several times higher compared to other ARs. Majority of concentrations were assumed to be sublethal, but in 15% of non-target species concentrations were so high that ARs could have contributed to the death of these individuals.

100
The fate of biocides in stormwater pond sediments
E.A. Rudelle, Aalborg University / Department of Civil Engineering; U.E. Bollmann, K. Bester, Aarhus University / Department of Environmental Science; A.H. Nielsen, Aalborg Unversity / Department of Civil Engineering; J. Vollertsen, Aalborg University / Department of Civil Engineering
Biocides are added to paints, wood preservatives, plasters, and other building materials to protect them against fouling. Upon application, biocides also ensure long shelf life of the product. However, biocides are slowly released, washed off during rain, and enter the stormwater flow, resulting in concentrations that routinely exceed quality standards set by the EC. Stormwater contains a range of other pollutants which are perceived as problematic. To mitigate their impacts, retention ponds are routinely used to treat the runoff prior to discharge into the environment. The objective of this study is to assess how selected biocides are sorbed and degraded in the organic-rich sediments of stormwater retention ponds. No study has hitherto reported the fate of biocides in retention ponds, and only few studies exists on pesticides in sediment from comparable systems. The sorption capacity, sorption kinetics, and degradation of Cybutryn, Terbutryn, Diuron and Carbendazim were investigated in microcosms simulating retention ponds. Stormwater sediments were deposited at the bottom of microcosms, and biocides were added. The removal of biocides from the liquid phase was monitored. After 3 weeks of incubation the sediments were extracted and analyzed for biocides. Parallel hereto sorption kinetics and stoichiometry was determined on the same sediments kept in suspension, the latter based on the relevant OECD standard. The total degradation of biocide was 10-30%, depending on biocide and sediment type. The sorption determined by slurry-tests and the microcosm tests did however not agree. The amount of biocide remaining in the liquid of the microcosms after 3 weeks were up to 10 times higher than what was expected based on the sorption capacities determined by the slurry tests. A fully dynamic diffusion-sorption-degradation box-model was applied to analyze this discrepancy. The simulations represented the measurements well and allowed dynamic distinguishing between degradadation and sorption. The study showed that all biocides underwent sorption and degradation in stormwater sediments to a degree where these processes will affect the final amounts discharged from retention ponds to receiving waters. It was furthermore observed that sorption kinetics of biocides in deposited sediments differed significantly from those of sediment slurries and that kinetics based on slurry experiments significantly over-estimated the sorption to retention ponds sediments.

101
Implementation of an Environmental Monitoring of Biocides to Follow Consequences of their EU Risk Assessment Outcome
H. Ruedel, Fraunhofer IME - Institute for Molecular Biology and Applied Ecology / Environmental Monitoring; M. Ahting, K. Michaelis, German Environment Agency Umweltbundesamt; K. Pohl, German Environment Agency Umweltbundesamt / Biocides
The implementation of the Biocidal Products Regulation (No. 528/2012; BPR) causes changes in the application of biocidal active substances and their entry into the environment. For biocides included in the list of approved substances concentrations may increase while decreasing environmental levels are expected for substances with non-approval decisions or implemented risk mitigation measures. Such consequences may be proven by an environmental monitoring. However, in most current monitoring programmes biocides are not appropriately covered yet. Traditionally, e.g. in surface waters mainly plant protection products (partly also approved as biocides) and legacy chemicals are monitored. In this context, the German Environment Agency (UBA) initiated a project which aims at developing a comprehensive monitoring concept for biocides which also includes selected monitoring studies. The developed prioritisation approach provides lists for a biocides monitoring in all relevant compartments (e.g. monitoring in surface waters: water phase, aquatic biota, suspended particulate matter/sediments). For the implementation of the proposed biocide monitoring approach mainly cooperation with existing programmes is recommended. At least some biocidal compounds are already covered (e.g., for surface water monitoring according to Water Framework Directive obligations). All proposed monitoring activities should be organised in a stepwise approach (e.g. screening study, survey in different regions, and inclusion in a routine monitoring programme). In a further part of the project archived biotic and abiotic samples from the German Environment Specimen Bank (ESB) were used for exemplarily retrospective monitoring studies to identify possible spatial and temporal patterns of selected biocides. As case studies monitoring data from recent investigations covering freshwater samples will be presented: e.g., cybutryne and tebuconazole in aquatic suspended particulate matter and rodenticides in fish liver tissue. Time series reveal sporadically occurrence of rodenticides such as brodifacoum in fish and decreasing levels of cybutryne (previously used as preservative in construction materials). Examples support the assumption that changes of the use of biocides after approval/non-approval decisions or as consequence of risk mitigation measures can be followed by an environmental monitoring. Appropriate monitoring data would also allow to check the appropriateness of exposure

estimations (verification of model outputs).

102
Biocidal active substances in households - reasons for the need to promote a sustainable use of biocides
S. Wieck, O. Olsson, Leuphana University of Lüneburg / Institute for Sustainable and Environmental Chemistry; K. Kuemmerer, Leuphana University Lüneburg / Institute of Sustainable and Environmental Chemistry
Households are a possible application site for a wide variety of biocidal active substances that fall under the Biocidal Products Regulation (EU) 528/2012 (BPR). However, the usage pattern of these substances there is widely unknown. Furthermore, the very same substances are used in products that are regulated by other regulations, too. As exposures resulting from different regulatory areas are currently not aggregated, the risks of these active substances will be underestimated. The objectives of the work presented here are therefore (i) to identify the biocidal active substances that can be found in households and the respective product categories they are used in and (ii) to describe the cases where biocidal active substances might enter the sewage system without being covered by the BPR and thus are not evaluated under its risk assessment scheme. Face-to-face interviews were conducted in 133 households in predominantly urban, intermediate and predominantly rural study sites in Germany. Members of private households were interviewed using a standardised questionnaire. Additionally, the products that were used in the households were registered with the help of a barcode scanner. Biocidal active substances were present in all households, eventhough not all posessed biocidal products, as the majority of uses of biocidal active substances was in washing and cleaning agents and personal care products, but not in biocidal products. Around 60 % of the registered applications of biocidal active substances do not fall under the risk assessment of the BPR. These can be active substances present in washing and cleaning agents, which are not assessed or approved for the use as in-can-preservatives. Furthermore, all biocidal active substances present in personal care products are not covered by the risk assessment of the BPR. The results show that gaps exist in the risk assessment of biocidal active substances. The attempt to solve the problem would require an extensive increase of complexity of risk assessments and their aggregation throughout all legislation. From our point of view, a better approach to reduce possible risks by these substances in general would be to limit their use to in fact essential usages. A sustainable use of biocides should thus be promoted to account for existing gaps in risk assessment.

Life Cycle Data and Modeling Developments - From Data Collection to Usage (II)

103
How to complete LCA studies data collection in order to improve its quality?
E. Lees-perasso, CODDE; A. Roy, Bureau Veritas CODDE; J. Orgelet, Bureau Veritas CODDE / EcoDesign; J. Garcia, P. OSSET, SCORE LCA
LCA is a more and more common and widespread tool used to calculate the environmental impacts of products and services. This importance leads to an increasing need for reliability and transparency of data and results. In parallel, the multiplication of LCA studies as well as the growing complexity of reference documents and analysed systems leads to an increasing need of temporal and human resources. Most of these are allocated to the collection and research of data to assess the systems considered. The time needed to perform this collection and the assessment is even greater as some data may be missing, hard to find or even false. Therefore, it is necessary to define and use methods in order to fill those gaps. Those choices are essential and must preserve the relevance and transparency of studies while limiting the need for resources. This presentation aims at introducing the study performed on behalf of the ScoreLCA association concerning how to answer this need for reliable methods of missing data gap completion. This study aims at answering this need through three steps: Describing existing reference documents requirements in terms of missing data Identifying, describing and applying actual or ongoing methods aiming at solving the data missing gap Determining recommendations allowing the selection and application of chosen methods, depending on the studied system typology and the LCA study goals Concerning the requirements, the study enlightened the different logical schemes about their implementation in the different documents, depending on the activity sector, the age of documents, and the involved actors and documents objectives. This study shows that the actual developments go towards a greater harmonization and complexity of requirements. Concerning the methods, the study concluded that the existing ones cover quite well the need for identification, analysis and substitution of missing data. Though, those methods have different application scope and advantages and drawbacks, due to inherent or external reasons. The LCA practitioners' difficulties reside in the selection and application of those methods. To go further, the study concluded on the importance to gather and analyse feedbacks from the different stakeholders (practitioners, verifiers, study users), as well as the methods and requirements answer thestudies objectives. This could provide a clear synthesis to be used as a basis for the development or update of future reference documents.

104
How to prioritize data collection based on uncertainty analysis: Application to the regionalization effort
L. Patouillard, CIRAIG - École Polytechnique de Montréal; P. Collet, IFP Energies nouvelles; P. Tirado Seco, CIRAIG; C. Bulle, CIRAIG - ESG - UQAM / Strategy   corporate social responsibility; M. Margni, CIRAIG - École Polytechnique de Montréal / Mathematical and Industrial engineering
Life cycle assessment (LCA) practitioners spent a lot of their time on data collection. A smart data collection insures a good study quality with low uncertainty. One of the main challenge for them is to focus effort on data that can reduce the overall uncertainty. Regionalization is one of the ways to reduce overall uncertainty. Life Cycle Inventory (LCI) regionalization deals with increasing the geographic representativeness modelled in LCI. Life Cycle Impact Assessment (LCIA) regionalization deals with calculating regionalized characterization factors (CF) that account for the spatial variability of the receiving environment for some environmental impacts. To use regionalized CF, elementary flows (EF) should be spatialized (LCI spatialization). Integrating regionalization requires additional effort on data collection and needs to be prioritized. This work proposes an operational methodology for LCA practitioners to prioritize data collection for regionalization purpose based on uncertainty analysis in order to select impacts, processes and EF that need further data collection. Its relevance and applicability is illustrated by a case study. The proposed methodology is stepwise, iterative and takes into account decision maker requirements to set the target for uncertainty reduction. It allows among other to prioritize the effort between LCI regionalization (if LCI uncertainty predominant) or LCI spatialization (if LCIA uncertainty predominant). Global sensitivity analysis tools are used to identifying uncertain sources that are the biggest contributors to the result uncertainty and that need further data collection. They have been selected based on a trade-off between accuracy and operationalization. For uncertainty contribution analysis (UCA), tools such as Contribution To Variance based Monte Carlo results and coefficient of variation (CV) are used. The proposed methodology has been tested on an ecoinvent v3 process using the IMPACT World+ LCIA method to investigated which aspects of this process should be regionalized. For water use impacts on human health, the relative importance of LCI and LCIA uncertainties are compared based on CV values. Main results show that the effort for data collection should be focus on information to spatialize water EF in order to use less agregated CF with a lower spatial variability. This methodology is described for regionalization purpose but could be further adapted for global data collection prioritization.

105
Influence of data choices in Life Cycle Assessment of waste management systems
T. Henriksen, Technical University of Denmark (DTU) / DTU Environment; T.F. Astrup, Technical University of Denmark / Department of Environmental Engineering; A. Damgaard, Technical University of Demark / DTU Environment
Environmental models, e.g. life cycle assessment (LCA), are widely used to support decision-making. An important factor for the reliability and usefulness of the models is to which extent they represent reality, i.e. the system of interest, which is influenced by the representativeness of the input data and the model itself. There are specific challenges for LCA of waste management systems related to the collection of representative data. Site-specific conditions affect the quality of the waste and the waste composition due to local waste separation and collection schemes, why there is a high need for site-specific data when modelling waste management systems. The objective of this paper is to evaluate the influence of input data choices in LCAs of waste management systems. The hypothesis is that data choices affect the LCA such that end result can vary with orders of magnitude. This is evaluated by analysing and comparing the spread of results calculated on basis of the modelling of a case study, where data combinations are implemented in the model. The case study is landfilling of Danish residual household waste with the functional unit being landfilling of 1 tonne of waste. A mechanistic landfill model was applied, where sub-processes are represented by modules and emissions are linked to the fractional and chemical waste composition. In the model, data choices were varied based on known ranges to represent different options for landfill gas and leachate generation and different types of technical collection and treatment solutions. A total of 864 data combinations were obtained, hence resulting in 864 results per impact category. From the preliminary results we saw a factor 2 spread between the minimum and maximum values of potential impacts of climate change, ozone depletion, ionizing radiation, fossil resource depletion and particulate matter. This highlights that data choices, even individual technology choices, influence the LCA results. By tracking the results back to its data combinations we found that the largest potential impact of climate change corresponded to a combination with high landfill gas generation and limited gas collection and utilization. Based on these preliminary results, it can be concluded that the choice and availability of representative data influence the LCA results, and thus that proper identification of the correct modelling choices is crucial within specific technologies.

Comparing models in estimating additive emissions from plastic materials in

use

T. Rydberg, J. Lexén, IVL Swedish Environmental Research Institute

The amount of additives in the total societal stock was previously estimated based on trade stastistics combined with product lifetime estimates and as detailed information "as possible" about the additive type, down to substances and their concentration in materials. Emissions for this amount was then estimated by two different emission models. The work presented here is a cross-comparison of these two models for calculating emissions of additives in polymer materials during the use phase of the materials. The purpose is to investigate if, at all, a rough model can be considered good enough. The actual product type used for the comparison is wall paint. An important reason for this selection was the fact that composition information for total volumes of wall paint was available through the chemical product registry at the Swedish Chemicals Agency. The substances included are functional additives in paint, i.e. preservatives, biocides, etc. Actually the cross-comparison could have been done also on a theoretical composition of some other product, but the overarching purpose of the work was to estimate the actual emissions of the additives at stake. The two models provide very varying results. When looking at the total emission estimate for the whole stock of plastics in the economy, it becomes clear that the rough model overestimates the emissions of additives when added together across all plastics and all additives. The advanced model, on the other hand, has been shown to provide a reasonably accurate estimate at least for specific substances (DINP from vinyl flooring) also when validated against concentrations in the indoor and outdoor environment. In this particular case the rough model overestimates emissions by a factor of 250. It is however highly uncertain to apply a similar factor for other materials and additives, as the emission ratio varies across several orders of magnitude. The rough model must therefore be considered "not good enough", while the advanced model needs further validation for more material/additive combinations.

107
A visual solution to optimize the understanding and exploitation of metadata from Open Data sources in LCA

B. Rugani, Luxembourg Institute of Science and Technology (LIST) / Environmental Research Innovation ERIN; P. Carvalho, B. Othoniel, T. Navarrete-Gutiérrez, Luxembourg Institute of Science and Technology LIST / Environmental Research Innovation ERIN

Metadata is a fundamental piece for the discovery and management of input datasets and methods in Life Cycle Assessment-LCA. Collaborative initiatives among LCA practitioners, database developers, data suppliers and other stakeholders worldwide have brought to several forms of metadata developments to improve the transparency of unit process datasets and impact assessment methods, providing the necessary knowledge on the applicability and relevance of data, helping reduce uncertainties and ensuring the reproducibility of LCA studies. The general impression is that the LCA practice is getting more and more oriented towards Open Access thinking, in particular for the use of life cycle commodity databases. Building on such free knowledge, however, can imply a lack of standardization, and pose additional problems to the consistency and quality of shared data. Hence, efforts to improve and harmonize metadata could reduce such issues. Information to build databases or update characterization models may be retrieved from open access portals, which can be valuable tools. The value of such information can even increase by using and combining datasets coming from different data sources. However, metadata from such sources, when defined, are not always easy to understand and exploit. This intensifies the complexity of searching and filtering datasets, which is one of the major challenges for database developers. Moreover, gathering datasets from different sources complicates the data collection because of different metadata policies, types and languages. While open data portals are more and more tailored to store large amounts of metadata, they are less effective in making data available. Such portals are not usually prepared to allow users downloading datasets, and not all of them use open formats (e.g. CSV and XML), limiting the dataset reuse. Thus, beyond the necessity to increase their readability, metadata need to be better exploited for more consensual, replicable and transparent dissemination and use of life cycle data. To this end, a novel visual technique is proposed here to organize in effective and friendly ways all metadata related to a group of life cycle datasets. This choice is made because data visualisation techniques allow rapid assimilation and recognition of large amount of information. For validation, a case study is presented with focus on an integrated modelling framework for the characterization of life cycle impacts on ecosystem services.

UNEP technical support on datasets review: a summary of learnings

B.W. Vigon, SETAC; A. Asselin, UNEP/Setac Life Cycle Initiative; G. Sonnemann, University of Bordeaux / The Life Cycle Group CyVi; A. Ciroth; S. CHEN, SIRIM Berhad; T. Braga, IBICT; N. Poolsawad, National Metal and Material Technology Center MTEC / LCA Lab; J. Mungkalasiri, MTEC; F. Boureima, L. Mila i Canals, UNEP

Introduction The UNEP/SETAC Life Cycle Initiative has developed the Global Guidance Principles for LCA databases [1] that describes guidelines for LCA databases to be interoperable and of adequate quality. To reflect thoses Principles, a review of 40 datasets has been conducted with UNEP support by independent LCA experts. Review process, timeline and criteria The whole effort had to be delivered in a set and limited timeline of six months and covered 40 datasets from emerging economies, 20 from Malaysia, 10 from Brazil and 10 from Thailand. The intent of the review was not to validate or not the sufficient quality of the datasets for publication, but rather to encourage improvements, either prior to publication or as part of a continuous improvement cycle. The developed review process consisted especially in i) d*eveloping a set of review criteria* for this specific effort, ii) establishing a *non-disclosure agreement (NDA)* between the data provider and reviewer and iii) providing a review report for each dataset that *assesses the presence, magnitude, and implications for qualifying usage regarding deficiencies relative to the criteria*, and iv) synthetizing a report on the review that overviews the effort, and integrates lessons learned. Results and discussion This exercise has been conducted in the given timeframe for the majority of the datasets. Challenges have been faced along the way, and among them : - *Agreeing on NDA* with data providers took more time than expected, due to countries' specific requirements; - *Need for sufficient information:* datasets have to be provided with detail of underlying unit processes, accompanied by the detailed description of what has been modelled and how; - The developed set of criteria for this exercise are not final review criteria for datasets: they are acknowledged as a starting point for further debates and improvements that should involve the broad LCA community. - Another question of interest raised during this exercise is the *confidentiality of the data*. Conclusions This hands-on exercise provided some valuable insights into the road towards global consensus and guidance on data review. Beyond this time-constrained effort, a broader discussion and consensus at international level on the review of datasets and a continuous effort in reviewing datasets is desirable. Investigating the Occurrence and the Fate of UV filters in Swimming Pools

T. Manasfi; B. Coulomb, J. Boudenne, Aix Marseille Université

Chemical UV filters belong to emergent organic compounds that are turning out to be a sticking point for both environmental and health concerns. Today, these compounds are used in increasing quantities and can be found in various environmental media. However, little is known about the occurrence of UV filters in seawater swimming pools and about their reactivity in presence of disinfectants such as chlorine. Determining the concentrations of UV filters in swimming pools and their transformation products is paramount to any risk assessment consideration especially that their potential halogenated byproducts could be toxic. For this reason, samples from two seawater swimming pools located in Southeastern France were analyzed to determine the concentrations of 5 widely used UV filters, namely dioxybenzone, oxybenzone avobenzone, octocrylene, and 2-ethylhexyl-4-methoxycinnamate (OMC). Additionally, the reactivity of the UV filters in the presence of different molar ratios of chlorine in seawater was examined and their byproducts were identified through laboratory-setting experiments. Samples were treated using liquid-liquid extraction and analyses were performed using ultra performance liquid chromatography-quadrupole time-of-flight mass spectrometer (UPLC/Q-ToF-MS) and using gas chromatography coupled to an electron-capture detector (GC-ECD). Identification of byproducts was conducted by accurate mass measurements. MS-MS experiments were also performed to elucidate structures of the found compounds. This work showed that the levels of UV filters in swimming pool samples varied considerably from one compound to another and from a pool to another. Samples from the non-chlorinated pool contained more than one UV filter while in the chlorinated pool only octocrylene was detected. The reactivity/stability of the UV filters also varied depending on the compound's structure. While dioxybenzone and oxybenzone were found to be the most reactive with chlorine, octocrylene was stable and did not react with chlorine even in presence of high levels of the latter. These differences in reactivity with chlorine among the UV filters might explain the results of the occurrence of UV filters in the chlorinated pool samples with only the stable UV filter octocrylene being detected. Chlorination by-products of the reactive UV filters were identified for the first time in this study and transformation pathways were proposed based on the identified byproducts.

110
Efficiency of reactive oxygen species in the degradation of the main synthetic musk compound: HHCB

l. lanceleur, IPREM CNRS UPPA / IPREM UMR CNRS; J. Cavalheiro, T. Pigot, IPREM UMR CNRS UPPA / IPREM UMR CNRS; M. Monperrus, Laboratoire de Chimie Analytique BioInorganique et Environnement LCABIE

Synthetic musk compounds are the dominant artificial fragrance compounds used as substitutes for natural musks. Due to their extensive use in personal care and household products, they are produced at the tonnage scale, which placed them on the list of chemicals for priority action (OSPAR, 2000). Recently, synthetic musks have raised considerable attention due to their persistence in the environment and hazardous potential to ecosystems even at low concentrations. Wastewater treatment plants (WWTPs) represent the major route of musk contamination into the aquatic environment. It has been recognized that these substances are only partially degraded during treatment process, and little is known about their transformation products that should be included in all assessments concerning musks' fate and toxicity. The aim of this work was to investigate the occurrence of synthetic musk compounds and their degradation products in WWTPs and to evaluate their fate during treatment processes. Experimentally, new advanced oxidation processes have been also evaluated for the degradation of the main synthetic musk compound (HHCB,Galaxolide®). Several treatments combining oxidative and photochemical processes have been tested and the formation/degradation of products were investigated using time series experiments. The results have identified efficient degradation pathways for wastewater treatment and highlight the need to focus on degradation products and their potential toxicological effects.

111
Comparison of UV/H2O2 and UV/S2O8 2- photolysis efficiency for the removal of estrogens in treated wastewater: chemical and biological assessment.
B. CEDAT, COMAP/INSA Lyon / LGCIE; h. metivier, C. de Brauer, INSA LYON
Conventional Wastewater Treatment Plants (WTPs) are not designed to treat organic micropollutants and can only partially degrade them. Amongst hundreds of detected molecules, endocrine disruptors compounds (EDCs) are found at very low concentrations (in the ng/L range) but often sufficient to induce biological effects due to their high estrogenic potency. The natural estrogens, estrone (E1), 17β-estradiol (E2) and the synthetic one, 17α-ethinylestradiol (EE2) are the most active and commonly found estrogens in wastewater. In a near future, WTPs will have to be upgraded as they are a major cause of EDCs discharge in the environment. Previous studies pointed out that UV/H?O? process was a feasible way to remove estrogens from surface water and wastewater in terms of removal efficiency and energy consumption. However, attention has been recently paid to sulfate radical-based advanced oxidation process. Endocrine disruptors such as Bisphenol A were shown to be better degraded by UV/$S_2O_8^{2-}$ than UV/H?O? but no study have been conducted using UV/$S_2O_8^{2-}$ photolysis for the oxidative removal of E1, E2 or EE2. Therefore, in the present study, UV/H?O? and UV/$S_2O_8^{2-}$ photolysis using a commercial low pressure (λ=254nnm) reactor were compared for the removal of a mixture of three hormones (E1, E2 and EE2) under semi-real conditions. Global estrogenic activity and single compound degradations were measured at the same time. The formation of various by-products that could potentially be more toxic or estrogenic than the original compound were assessed by YES bioassay (estrogenic activity) and *Vibrio fischeri* bioassay (acute toxicity) for each treatment in treated wastewater. Treated wastewater was obtained from a local WTP (Feyssine, Lyon) and spiked with hormones at 5 μM. Hormones removal was measured by UHPLC-UV. UV in combination with H?O? or Persulfate led to a fast estrogenic activity removal. However, global estrogenic degradation constant was 2.43 times faster following UV/$S_2O_8^{2-}$ photolysis than UV/H?O? photolysis. Degradation constants of single compounds were between 2.34 (E1) and 3.9 (E2) faster following UV/$S_2O_8^{2-}$ treatment. Both treatment could enhance hormones and global estrogenic activity removal at the same time but UV/$S_2O_8^{2-}$ was more efficient at equimolarity. No estrogenic or toxic by-products were detected.

Advantages of wastewater treatment plant upgrading with additional activated carbon for ecosystem health
S. Wilhelm, Universität Tübingen / Department of Biology Animal Physiological Ecology; A. Henneberg, D. Maier, University of Tuebingen / Department of Biology Animal Physiological Ecology; R. Triebskorn, University of Tuebingen / Animal Physiological Ecology
Aquatic organisms have to cope with a variety of anthropogenic substances continuously released into the aquatic environment. In order to reduce surface water pollution, new wastewater treatment plant technologies have been developed during the last years. However, little is known about their efficiency with respect to ecosystem health. The BMBF project SchussenAktiv*plus* examined the efficiency of different wastewater treatment technologies and the resulting advantages for the ecosystem. For this purpose, different chemical and biological analyses were conducted prior to and after the application of new technologies to several wastewater treatment plants and rainwater overflow basins connected to the Schussen River, a major tributary of Lake Constance. Another tributary, the Argen River, served as a reference. The present study is integrated into the follow-up project SchussenAktiv*plus*+ and focuses on the long-term effects of the additional activated charcoal stage at the wastewater treatment plant Langwiese (Ravensburg, Germany) for the ecosystem of the Schussen River, with special focus on fish health. In order to assess endocrine and toxic effects in fish, different biological analyses were conducted prior to and after the upgrade. Thus, the induction of vitellogenin, the induction of micronuclei in blood cells, EROD activity, and fish development were examined. Overall, the results imply a positive impact of the additional activated charcoal stage for the ecosystem of the Schussen River.

Biological treatment of micropollutants in drinking water resources
J. Wittebol, M.H. Wagelmans, Bioclear
Contamination of drinking water resources is becoming a threat that is particularly widespread. Micropollutants are emerging substances in surface and groundwater causing contamination of drinking water resources and ultimately to closing down groundwater abstraction wells. BIOTREAT is a European project in which *sustainable biotechnologies* are developed for remediation of drinking water resources based on bioaugmentation, introduction of specific degrading microorganisms or microbial consortia into existing sand filters at waterworks or mobile filters. The compound BAM (2,6 Dichlorobenzamide) was chosen as model compound. Based on results of laboratory tests, a total of 6 submerged sandfilter columns were operated, of which 2 none-inoculated controls and two columns that were exposed to 1 μg/L BAM and two to 30 μg/L BAM (all inoculated with MSH1). Start-up retention time was 120 hours and the operation time of the experiment was 240 hours. No back-flushing was applied. Results show that in the 1 µg/L BAM exposed columns, BAM degradation up to 72% was established. In the 30 µg/L BAM exposed columns, 99% degradation was achieved. Well relocation is the cheapest scenario in case of pollution with micropollutants. But the well replacement scenario is only cheaper if the new well is placed within a few kilometers from the water production plant (3.5 kilometers for the 800,000 m^3 water production per year). If clean water is more than a few kilometers away, implementing a BAM removal strategy becomes the best solution. For the large drinking water production volumes a GAC filter is the cheapest BAM removal technique. BIOTREAT bio-augmentation technology + carrier is the most attractive technology for small scale drinking water production plants. Compared to traditional physicochemical technologies, biological technologies have the advantage that: - Natural resources are used. - No harmful chemicals are used, use of contaminated groundwater for drinking water production is made possible which otherwise might remain unused. - Application is low cost compared to traditional physicochemical technologies. - Technology is plug and play. No additional infrastructure needed at waterworks. - Compound specific removal is possible. Based on a production facility of 800.000 m^3 per year the operating costs for these technologies, bioaugmentation and bioaugmentation + carriers, are € 0.20/m^3 and € 0.11/m^3 respectively.

114
Triclosan, triclocarban and parabens in greywater: identification of their sources.
s. zedek; A. Bressy, S. Deshayes, Paris-Est University / Leesu; V. Eudes, Labratoire Central de la Préfecture de Police; E. Caupos, Université ParisEst LEESU UMRMA UPEC ENPC AgroParisTech UPEMLV / Leesu; R. Moilleron, Paris-Est University / Leesu
The use of soaps, shampoos or other personal care products (PCPs) generates discharges of chemicals into the environment through grey- and wastewater. Among these chemicals, parabens (PBs), triclosan (TCS) and triclocarban (TCC) are widely used in the composition of PCPs but also in sportive clothes, pharmaceuticals and food products as antiseptic or conservative. In a previous study several kinds of greywater from shower, washbasin, manual dishwashing, dishwasher and washing machine have been analyzed. The key lessons highlighted by this work were that (i) greywater strongly contributes to the contamination of wastewater and (ii) washbasins, showers and more surprisingly washing machines are the main contributors (in loads, μg/inhabitant/day) to the contamination of wastewater. PCPs are not therefore the only source of parabens and triclosan in wastewater: dishwashing and washing machine samples appeared as contaminated as shower samples. To reduce micropollutants at source, a better knowledge of the origin of greywater contamination is needed. The identification of the origin of the contamination was assessed through the decomposition of waters from washing machine (n=4) and shower (n=4) into four types of samples (1, 2, 3 and 4). Consequently, several potential sources were investigated: **washing machine:** tap water (1), washing machine (2), laundry products (3) and clothes (4); **shower:** tap water (1), bathtub (2), personal care products (3) and volunteer (4). First, whatever the compound, the tap water appears to be not or very slightly contaminated by TCC and PBs. In the same way, the contribution of the bathtub appears to be negligible. Concerning MeP, EtP and PrP, the main contributors are the products (55, 68 and 62 % respectively) and the body (39, 32 and 35 % respectively). For BzP and TCC, products are the only source of contamination. PBs and TCC are used as antiseptic or conservative in numerous PCPs, including toothpastes, soaps, deodorants and cosmetics products which led to the important contribution of products to the whole contamination. However, the striking contribution of the body was more surprising meaning that an important part of the contaminants (MeP, EtP and PrP) arises from the skin. Three hypothesis have been advanced to explain our results: after the use of PCPs, a part remains on the skin; a deposition on the skin of air dust containing PBs and TCC; and a transfer of contaminants from clothes to skin.

Ecotoxicology and risk assessment of nanomaterials - Interactions at nano-bio interface (I)

115
Tracking nanomaterial targeting and uptake by SUSTU, protein corona surface proteomics
S. Cristobal, Linköping University / Department of Cl and Exp Medicine Cell Biology; A. Farinha, Linköping University / Clinical and Experimental Medicine Cell Biology; N. Bayat, Stockholm University / Biochemistry and Biophysics; J. Kuruvilla, Linköping University / Clinical and Experiemental Medicine
The nanosafety of any newly developed nanomaterial should be studied through its evolution and aging upon interaction with environmental or biological samples rather than at the stage of newly synthesized entity. One of those key elements is the understanding of the nano-bio-eco interphase. The nature of the protein corona (PC) in contact with different biological environments has been extensively reported [1-3]. Nevertheless, less few studies addressed the evolution of the PC in terms of how the transition from an extra- to intra-cellular environment can modulate its biological identity and physicochemical properties [3, 4]. By understanding the key questions to be addressed from a new synthesized nanomaterial we can focus our analysis in the minimal set of data that would provide that information. Following this shortcut strategy we have developed, SUSTU, a surface proteomic method for tracking nanoparticle targeting, uptake and safety based on nanoparticle protein corona. The objective of this work are: i) develop methodologies that can define the specific enrichment of the PC surface, and iii) integrate MS-based PC data to develop nanointeraction tools for nanosafety. The method developed is highly reproducible between biological and experimental replicates. The key steps has been considered in the method development to be able to compare the data from the entire corona to the surface. By comparing the quantitative analysis of entire protein corona to the surface protein corona, we confirmed that the distribution of proteins in the surface is followed different pattern than in the entire corona. The protein concentrated in the surface are not equally distributed in the internal core of the corona. We could define a set of proteins that could be involved in targeting and other set that are not exposed to interaction with biological systems. We discussed the biophysical difference among the proteins composing the surface and the entire corona and the biological implication at the level of targeting and uptake capability and nanosafety at destiny.

116
Algal toxicity of platinum nanoparticles - Implications of NP aggregation, dissolution and shading
S.N. Sørensen, DTU Environment / Department of Environmental Engineering; C. Engelbrekt, Technical University of Denmark / Department of Chemistry; H. Lützhøft, Technical University of Denmark / Department of Environmental Engineering; J. Jiménez-Lamana, University of Geneva / Section of Earth and Environmental Sciences Institute Forel; J. Noori, Intelligent Pollutant Monitoring; F. AlZahraa Alatraktchi, Technical University of Denmark / Department of Micro and Nanotechnology; C. Giron Delgado, Technical University of Denmark; V. Slaveykova, University of Geneva / Section of Earth and Environmental Sciences Institute Forel; A. Baun, DTU Environment / Department of Environmental Engineering
Platinum nanoparticles (PtNPs) are used in automotive catalytic converters and emitted to the environment during use. The resulting aquatic toxicity of PtNPs remains largely unknown. Algal growth rate inhibition has been reported, however, this endpoint is substantially influenced by PtNPs shading effects, and it is unclear if any toxic mechanism(s) are involved. Present study elucidates the mechanisms involved in the algal growth inhibition caused by PtNPs by comparing different toxicity endpoints in two algal species and media, including influence of NP shading, dissolution, aggregation, and adhesion to algal cells. Algae were exposed to $PtCl_4$ and 5.7 nm starch stabilized PtNPs in standard growth rate inhibition tests (ISO 8692:2004) with 48h incubation and a 2h C-assimilation test with the green algae *P. subcapitata* and *C. reinhardtii*. Shading effects were studied using a double-vial setup, containing algal cells in inner vials, surrounded by PtNPs in larger outer vials. After 2, 24 and 48h, oxidative stress and cell membrane damage were determined by flow cytometry and body burdens of PtNPs (Pt mass/cell) determined using a coulter counter and ICP-MS analysis of cells captured on filters. Characterization included size distribution (AsFlFFF, NTA, DLS), dissolution (ultracentrifugation), sedimentation (UV-VIS) and abiotic ROS generation (fluorescent dye, UV-VIS). PtNPs inhibited growth rates of the algae in the standard test and slightly less in the double-vial shading setup, suggesting that shading occurs but that PtNPs inhibits growth by other means than shading. In the 2h C-assimilation test, inhibition was similar using the standard or the double-vial setups, thus inhibition was solely ascribed to shading, making this test inappropriate for testing PtNP-toxicity. If PtNP concentration-response curves were based on dissolved fractions, higher toxicity was found than accounted for by the ionic Pt, suggesting a NP-specific effect. *P. subcapitata* was more sensitive to $PtCl_4$ and PtNPs and was shaded more, than *C. reinhardtii*, which correlates with a greater measured body burden of PtNPs in *P. subcapitata*, which again might be related to less PtNP aggregation in the ISO media. PtNPs caused extensive oxidative stress, but little membrane damage. *P. subcapitata* was less affected than *C. reinhardtii*, which is opposite to the growth rate inhibition tests. Thus, growth rate inhibition and oxidative stress do not appear linked in a straight forward manner.

117
Mechanistic understanding toward the toxicity of graphene-family materials to freshwater algae
Z. Wang, J. Zhao, H. Zheng, X. Luo, Ocean University of China; B. Xing, University of Massachusetts - Amherst / College of Natural Sciences
In this work, we systematically investigated the toxicity of graphene-family materials (GFMs) including graphene oxide (GO), reduced graphene oxide (rGO) and multi-layer graphene (MG) to alga (*Chlorella pyrenoidosa*). GFMs exhibited much higher toxicity than other carbon materials (e.g., carbon nanotube and graphite), with the 96 h median effective concentration (EC_{50}) values of 37 (GO), 34 (rGO), and 62 (MG) mg/L. Heteroagglomeration between GFMs and algal cells contributed to algal growth inhibition. rGO and MG were easier to agglomerate with alga than GO. Cell membrane was damaged after GFMs exposure as indicated by the increased leakage of K^+ and DNA, and rGO caused the highest damage. Oxidative stress and physical penetration were responsible for the observed membrane breakage. For GO, shading effect contributed approximately 17% of growth inhibition due to its higher dispersibility while the other GFMs did not show any shading effect. All the three GFMs adsorbed macronutrients (N, P, Mg, and Ca) from the algal medium, leading to nutrition depletion and indirect toxicity. For GO, rGO, and MG, the contribution of nutrition depletion to growth inhibition was 53%, 35%, and 27%, respectively. The information provided in this work will be useful for understanding the environmental risk of graphene materials in aquatic environments.

118
Internalization and toxicological mechanisms of uncoated and PVP-coated cerium oxide nanoparticles in the freshwater alga Chlamydomonas reinhardtii
G. Pulido-Reyes, Universidad Autónoma de Madrid; S.M. Briffa, University of Birmingham / School of Geography Earth and Environmental Sciences; F. Leganes-Nieto, Universidad Autónoma de Madrid / Biology; V. Puntes, Institut Català de Recerca i Estudis Avançats ICREA / Experimental Science and Mathematics; E. Valsami-Jones, University of Birmingham / School of Geography Earth and Environmental Sciences; R. Rosal, University of Alcala; F. Fernandez-Piñas, Universidad Autónoma de Madrid / Biology
Cerium oxide nanoparticles (CNPs, nanoceria) are increasingly used in industrial applications and may be released to the aquatic environment, where the exposure of aquatic organisms becomes likely. There are contradictory reports on whether nanoceria may act as an oxidant causing toxicity[1] or as an antioxidant being able to scavenge free radicals[2], given that the toxicological behaviour of these nanoparticles is still poorly understood. Moreover, little is known about the internalization process of CNPs in algae. There is evidence of CNP-internalization by *Chlamydomonas reinhardtii* (*C. reinhardtii*), but the internalization mechanism and route of uptake are still unknown[3]. In this study, we used an uncoated and different polyvinylpyrrolidone-coated CNPs (the purpose of the coating being to improve their stability, by inhibiting aggregation) with the aim of identifying their internalization and toxicological mechanisms. Monodispersed nanoparticles were synthesized and physicochemically characterized both in distilled water and the exposure media. Nanoparticles coated with PVP, irrespective of PVP molecular weight, had higher growth inhibition to *C. reinhardtii* than bare CNP. PVP-CNPs significantly increased ROS formation in exposed cells, indicating that oxidative stress might be an important toxicity mechanism. Interestingly, there was evidence of membrane disruption upon nanoparticle exposure, suggesting that membrane permeability might increase; thus, allowing internalization of nanoparticle. At present, the mechanisms of CNP-internalization are under thorough study. 1. Pulido-Reyes G, Rodea-Palomares I, Das S, Sakthivel TS, Leganes F, Rosal R et al. Silver nanoparticles vs. dissolved silver toxicity to Daphnia magna: Unique modes of action?
K.B. Paul, Blue Frog Scientific Limited / SLS; D. Brown, Heriot-Watt University; D. Carson, Blue Frog Scientifiic Limited; T.L. Hargreaves, Blue Frog Scientific Ltd / Environmental Science Ecotoxicology; V. Stone, Heriot-Watt University / School of Life Science; T.F. Fernandes, Heriot-Watt University / School of Life Sciences
Disturbances in genes or biochemical regulation of an organism can often be seen at lower doses or on shorter time scales than whole body effects, and are a

precursor for whole body manifestations of a toxicant and population level effects therein, and thus are detected sooner than such endpoints as immobility. If we are able to predict effects prior to whole body manifestations through more sensitive screening we are able to better protect the environment. For nanoparticles (NPs) the best biochemical endpoints, and those most relevant to highlight exposure to NPs, still remain elusive. For instance, it is still uncertain if silver NPs (Ag NPs) have a distinct mode of action (MOA) from dissolved Ag (d-Ag) within the aquatic environment; this is despite a large body of research. d-Ag acts at the Na^+K^+-ATPase ligand, causing osmoregulatory failure and mortality mainly through an imbalance of sodium and potassium. Many NP studies show that oxidative stress may be the main driver of NP toxicity. Contradictory research often arises from researcher postulation based on standard test results (i.e. mortality/ reproductive tests) coupled with interpretation of the NP physicochemical characteristics with no evidence at the biochemical level of the interaction at the biophysical interface, or indeed if there is a common interaction interface between the two forms. Here we used a series of biochemical tests to identify differences and/or similarities between Ag NP and d-Ag toxicity and their MOA, in particular we measure whole body cation levels to see if distinct MOA were present from that traditionally noted for d-Ag. We also assess if the degree of effect correlates with the degree of effect seen for 3 different Ag NPs and dissolved silver (as $AgNO_3$) in acute bioassays. d-Ag caused physiological perturbations in cation levels as previously noted in the literature. Ag NPs affected mitochondrial function which led to perturbations in ATP and increased super oxide with a concurrent rise in super oxide dismutase in cellular defence. The degree of effect for immobility and biochemical changes were similar in some instances. Based on the results we present a flow chart of possible physiological reactions which lead to eventual population impacts. We discuss the possibility of a common MOA across many species based on the current state of knowledge for Ag NPs. Such knowledge may lead to more specific and better testing strategies for Ag NPs.

Development of a multimodal imaging approach of Ag-NP interactions with Raphidocelis subcapitata

R. Sekine, NERC Centre for Ecology and Hydrology / Ecotoxicology; K.L. Moore, The University of Manchester / School of Materials; M. Matzke, Centre for Ecology & Hydrology (NERC) / Molecular Ecotoxicology; E. Donner, University of South Australia / Centre for Environmental Risk Assessment and Remediation; C. Svendsen, CEH, Wallingford / Pollution and Ecotoxicology; C.R. Grovenor, The University of Oxford / Department of Materials; E. Lombi, University of South Australia / Future Industries Institute

Abstract Nanotechnology has seen tremendous advances over the last few decades and has found applications in a diverse spectrum of industries, ranging from cosmetics, medical diagnostic imaging, and forensics, to energy and catalysis. These applications exploit the unique properties that arise when materials are manufactured at the extremely small size that is referred to as 'nanoscale'. Importantly, it is now recognised that due to their small size and high surface area, engineered nanomaterials (ENM) may interact in a distinct manner with living organisms in the environment. However, techniques that are capable of elucidating the interactions of ENMs with livings systems (the bio-nano interactions) are currently critically limited and are in high demand [1]. This is a serious research challenge given the inevitability of ENMs release into the environment by the development and use of ENM-containing products. The aim of this study was to develop a methodology enabling imaging of bio-nano interactions between silver nanoparticles (Ag-NPs) and the algae *Raphidocelis subcapitata*, a model organism in toxicity studies. Of the thousands of ENMs that have been identified in the consumer market [2], Ag-NPs dominate in their occurrence and are hence the most likely ENMs to enter the environment. Silver is known to be toxic towards a variety of organisms, and for this reason their risk assessment has been of particular focus in many studies. We used a multimodal approach combining dark-field light microscopy, scanning electron microscopy (SEM) and nanoscale secondary-ion mass spectrometry (NanoSIMS) imaging to investigate the interaction of surface functionalised Ag-NPs with the *R. subcapitata* cells. By using the dark-field light microscope and high resolution SEM, we identified the presence of Ag-NPs in the peripheral of the algae, and confirmed its chemical identity using NanoSIMS imaging. The advantages and limitations identified for each technique in determining the localisation of NPs in single organisms will be presented and directions for future improvements in this combined approach will also be discussed. **References** [1] Schaumann, G. Flame Retardants: Alternatives, Environmental Fate and Toxicity (II)

121
From clothing to laundry water: Investigating the fate of flame retardants and plasticizers sorbed to fabrics.

A. Saini, University of Toronto / Department of Physical and Environmental Sciences; C. Thaysen, University of Toronto; L.M. Jantunen, Environment Canada / Air Quality Processes Research Section; R. McQueen, University of Alberta; M.L. Diamond, University of Toronto / Department of Earth Sciences

Our indoor environment contains large inventory of products that contain semi-volatile chemicals of concern such as flame retardants and plasticizers. Over time, these chemicals, which are added but not chemically bonded to polymers, are released from those products and accumulate in the various media within the indoor environment such as dust and fabrics. We report on first, the partitioning from air-to-fabric and then the loss of chemicals sorbed onto fabrics through laundering. Analytes of interest were organophosphorus (OPFRs) and brominated flame retardants (BFRs) and phthalates. Cotton and polyester fabrics were deployed in an office at University of Toronto for 30 days followed by their laundering and analysis by GC-MS to compare total mass sorbed, mass released in laundry water, and mass remaining on fabrics after laundering and drying. Results showed that fabrics accumulated all analytes tested. More than >70% of sorbed OPFRs, such as TCEP and TCPP, were lost from fabric to laundry water whereas this value was < 10% for BFRs. Rather, BFRs remained sorbed to fabrics after laundry and drying. These results are interpreted in terms of chemical fate indoors and outdoors. The results can explain, in part, the source of elevated concentrations of OPFRs in waste water streams and eventually receiving surface water bodies (e.g., Schreder et al. 2014). Thus, our clothing (or fabrics) can act as a pathway for ecosystem exposure and/or transfer of COCs from indoors to outdoors.

122
Organophosphate and Brominated Flame Retardants in Human Hair and Nails

A. Salamova, Indiana University / SPEA; L. Liu, Indiana University / School of Public and Environmental Affairs; K. He, Indiana University / School of Public Health; R.A. Hites, Indiana University / School of Public Environmental Affairs

After the phase-out of polybrominated diphenyl ethers (PBDEs), the use of alternative flame retardants (AFRs), such as FireMaster 550, and of organophosphate esters (OPEs), has increased. However, little is known about human exposure to these chemicals. This lack of biomonitoring studies is partially due to the absence of reliable non-invasive biomarkers of exposure. Human hair and nails can provide integrated exposure measurements, and as such, these matrices can potentially be used as non-invasive biomarkers of exposure to these flame retardants. Paired human hair, fingernail, toenail, and serum samples obtained from 50 adult participants recruited at Indiana University Bloomington were analyzed by gas chromatographic mass spectrometry for 36 PBDEs, 9 AFRs, and 12 OPEs. BDE-47, BDE-99, 2-ethylhexyl-2,3,4,5-tetrabromobenzoate (TBB), di(2-ethylhexyl) tetrabromophthalate (TBPH), *tris*(1,3-dichloro-2-propyl)phosphate (TDCIPP), and triphenyl phosphate (TPHP) were the most abundant compounds detected in almost all hair, fingernail, and toenail samples. The concentrations followed the order: OPEs > TBB+TBPH > Σpenta-BDE. PBDE levels in the hair and nail samples were significantly correlated with their levels in serum ($P < 0.05$), suggesting that human hair and nails can be used as biomarkers to assess human exposure to PBDEs.

123
Impurities of resorcinol bis(diphenyl phosphate) in plastics and in dust

A. Ballesteros-Gomez, VU University Amsterdam / Chemistry and BiologyIVM; . AragÃn, VU University Amsterdam / IVM Chemistry and Biology; N. Van den Eede, University of Antwerp, Toxicological Center; J. de Boer, VU University Amsterdam / Institute for Environmental Studies; A. Covaci, University of Antwerp, Toxicological Center / Toxicological Center Dept of Pharmaceutical Sciences

Flame retardants are added to a variety of materials (electronic equipment, textile, furniture, etc.) in order to prevent quick combustion and to delay the spread of fire. After the phase-out of polybrominated diphenyl ethers (PBDEs), phosphorus flame retardants (PFRs) have been increasingly used as suitable alternatives. However, concern about their widespread presence and potential toxicity has also increased in the last years.Resorcinol bis-(diphenylphosphate) (RDP) is a PFR widely used in electric and electronic equipment and ubiquitous in house dust according to recent literature. Similar to other flame retardants, RDP formulations and products treated with RDP can contain impurities, byproducts and breakdown products that could influence the total toxicity of RDP formulations. In this study, we investigate the presence of RDP impurities in plastics from electrical/electronic equipment and in indoor dust collected on electronics, in order to study the possible migration of these compounds into the environment. A variety of RDP-related products, such as *meta*-HO-triphenyl phosphate (*meta*-HO-TPHP), RDP with the loss of a phenyl ring (RDP-[Phe]) and meta-HO-RDP were observed in both plastic and dust samples collected on/around electronics. Regarding the dust samples (n=30), the detection frequency of the compounds were in the order TPHP (n=30), RDP (n=27), meta-HO-TPHP (n=25), RDP-[Phe] (n=8) and meta-HO-RDP (n=5). The concentrations measured in dust for the three compounds for which standards were available (222-50,728 ng/g for TPHP, 23-29,118 ng/g for RDP and 20-14,227 for meta-HO-TPHP) are in agreement with those previously reported for RDP and TPHP and for other FRs in samples collected on/around electronics . The high levels of RDP, TPHP and meta-HO-TPHP (reaching the ӝg/g levels) that were found in some of the dust collected on electronics suggest that dust could be a significant route of human exposure to these compounds via ingestion/dermal adsorption. This could happen especially when touching these surfaces, e.g. switching on a TV or a router. Giving these first results, more data on the presence and potential toxicity of meta-HO-TPHP (and of other RDP impurities) is necessary in future monitoring studies to assess the human exposure and risks of RDP related compounds. Besides, due to its specificity and ubiquity as RDP impurity, meta-HO-TPHP could be a suitable marker/tracer of RDP

124
Toxicological mechanisms of current flame retardants
B. Krivoshiev; F. Dardenne, Universiteit Antwerpen; R. Blust, University of Antwerp / Systemic Physiological and Ecotoxicological Research Department of Biology; A. Covaci, University of Antwerp, Toxicological Center / Toxicological Center Dept of Pharmaceutical Sciences; S. Husson, Systemic Physiological and Ecotoxicological Research group - University of Antwerp
Flame retardants (FRs) are chemicals produced at high volume that are introduced to nearly all manufactured materials with the purpose to limit fire hazard. Given their persistence and potential to bioaccumulate, the compounds have been found in serum and breast milk. Toxicological data is largely limited to monitoring classical endpoints such as measuring lethal dose values. Therefore there is little insight into their molecular modes of action that may give rise to their toxic phenotypes. Additionally, some previously-used FRs have been shown to elicit a wide range of toxicological effects and have thus been banned from use. Given the structural similarity to their toxic predecessors, their persistence, bioaccumulation, and lack of insight of toxicological and molecular mechanisms, currently-used FRs pose a significant risk. We therefore used a bacterial gene profiling assay to screen 12 currently-used FRs as to obtain mechanistic insights of toxicity. Bacterial biosensors are frequently used to assess ecotoxicological impacts of compounds since they are particularly useful in compound screening and classification according to mode of action. The assay consists of 12 bacterial reporters (*Escherichia coli*) responsive to oxidative stress, protein degradation, DNA damage, membrane damage, and growth arrest. Both brominated and organophosphate FRs were tested. Nearly all compounds showed significant inductions in a majority of stress genes when compared to control treatments. When observing only raw absolute induction levels, the stress genes *ClpB*, *RecA*, and *MicF* were the only genes exhibiting fold inductions of greater than 2, indicating that these compounds result primarily in protein, DNA, and membrane degradation. However, accounting for the different induction potentials for each stress promoter and clustering using hierarchical and k-means algorithms, clusters corresponding to growth arrest and oxidative damage were also observed. This indicates that FRs may result in a loss of protein, DNA, and membrane integrity with generation of reactive oxidative species as the potential underlying mechanism, in agreement with other studies. Finally, the lack of any notable gene induction following DOPO treatment even at extremely high concentrations, along with its excellent fire-retardation supports its increasing interest as an alternative to halogenated FRs.

125
Species differences in steroid hormone receptor responses
P. Olsson, S. Asnake, C. Modig, Orebro University / The Life Science Center
Endocrine disrupting chemicals present in the environment can have differences in efficacy and potency when interacting with steroid hormone receptors from different species. This is due to both species variations in sequence and endogenous hormone utilization. There are a number of brominated flame retardants (BFRs) for which there are no information on their interactions with biological systems. We have been characterising BFRs using a combination of *in silico* molecular modelling, in vitro assays and in vivo studies. In an *in silico* analysis of 10 model BFRs we identified one of the test compounds, 1,2-dibromo-4 (1,2 dibromomethyl) cyclohexane (TBECH) as a partial androgen receptor (AR) agonist. TBECH is an interesting compound as it has 4 different diastereomers (α, β, γ, δ) each with its own enantiomer. In a follow up study we compared the efficacy and potency of the TBECH diastereomers and discovered that TBECH-γδ exhibited the same efficacy and potency as the endogenous androgen, DHT, while TBECH- αβ induced AR to about 30% of maximal activity. Continued screening using in silico methodology has resulted in the discovery of yet another group of BFRs that interact with the human AR. These are 2,4,6-tribromophenyl ether (ATE) and 2,3-dibromopropyl 2,4,6-tribromophenyl ether (DPTE) and the metabolite 2-bromoallyl 2,4,6-tribromopheyl ether (BATE) that we recently showed to be potent AR antagonists. As different species use different androgens we then focused on determining the ability of these novel BFRs to interact and regulate the activity of AR in different species as well as to determine if they interact with other steroid hormone receptors in a species-specific manner. TBECH was found to activate both the zebrafish AR and the chicken. However, the activation potency was lower than that observed for the human AR. TBECH-γδ induced a 40% increase in zebrafish and only about 15% in chicken. TBECH- αβ, that showed about 30% induction in human AR showed minimal induction of zebrafish and chicken AR at the maximum TBECH concentration. ATE, BATE and DPTE were equally potent at inhibiting AR signalling in human, zebrafish and chicken. Following the identification of these BFRs as AR agonists/antagonists we also used *in silico* modelling and analysis of transcriptional regulation and observed that these compounds also regulate other steroid hormone receptor pathways, including the oestrogen receptor and thyroid receptor signalling pathways.

126
Determination of the eco-toxicological risk of eluates of reactive flame retardants
N. Bandow, Federal Institute for Materials Research and Testing / Contaminant Transfer and Environmental Technologies; S. Gartiser, I. Heisterkamp, Hydrotox GmbH; U. Kalbe, BAM Federal Institute for Materials Research and Testing / Contaminant Transfer and Environmental Technologies
Flame retardants are increasingly used in consumer products as e.g. electronics and furniture as well as in construction. Along with the increased usage, concerns about negative effects of flame retardants on human health and the environment have been raised. Concerning construction products one application for flame retardants is the furnishing of steel structures with reactive flameproof coatings. These coatings consist of a complex mixture of different chemicals, additives and solvents. For the evaluation of the risk possibly posed by their application to the environment, this whole mixture should be tested. Two different leaching tests were applied according to DIN/TS 16637-2 (sample permantly submerged in water) and DIN EN 16105 (immersion and drying cycles), respectively, which can be used for plate-like products. Eluates were divided into subsamples for the measurement of different parameters: pH-value, conductivity, total organic carbon (TOC), cation and anion concentration. For screening of organic compounds, aqueous samples were liquid/liquid extracted using three solvents with different polarity (toluene, hexane and ethylacetate). GC-MS chromatograms were recorded in the SCAN mode and mass spectra of the peaks were compared with spectras stored in the NIST library. Eluates of leaching test accroding to DIN CEN TS 16637-2 showed low electrical conductivity (20 to 150 µS/cm) and low release of cation and anions often near the LOQ. Diffferences could be observed for plates treated with the reactive coating at both sides and plates coated only at one side, while the other side is only furnished by the corrosive protection layer. Release of TOC and Zn was approx twice or 10 fold higher in the case of plates coated on one side. Furthermore, the comparison of the results for both types of plates showed that a large portion of the released compounds originate rather from the corrosion protection layer than from the reactive coating itself. Leaching tests according to DIN EN 16105 have not been finished yet, but first results show that the conductivity is much lower (1-4 µS/cm) than for the tests according to DIN/TS 16637-2 leading to the assumption that the release of compounds is lower. By comparison of the mass spectra with library data, mainly organic solvents as xylene, 1-methoxy-2-propanol acetate and n-btuyl carbamate have been tentatively identified so far in the first test fraction done by DIN CEN TS 16637-2.

Microplastics in the environment: Sources, Fate and Effects (III)

127
Interactions of non-polar organic compounds with polyethylene and polystyrene micro particles
T. Hüffer, T. Hofmann, University of Vienna / Department of Environmental Geosciences
Concerns about the presence of micro scale polymers (i.e., microplastics) in environmental system are rapidly growing. Understanding the interactions between microplastics and other contaminants is thus essential for evaluating the materials' fate. Additionally, sorption of organic compounds by microplastics is one of the major processes as it may affect the compound distribution in sediments and aqueous phases. However, there is currently little data on the sorption potential of diverse sets of hydrophobic organic compounds/microplastics systems that may occur in the environment. We applied a multi-phase sorption batch method to investigate the sorption of seven organic compounds by two most commonly found microplastics. Experimental sorption isotherm data by polyethylene (PE) and polystyrene (PS) measured over several orders of magnitude were fit to the non-linear Freundlich model to support mechanistic interpretations of the results. Correlation between sorption coefficients by microplastics and sorbates hydrophobicity indicates that hydrophobic interactions are of major importance. Linear isotherms by PE shows that uptake was driven by adsorption into the bulk polymer, while adsorption onto the surface seems to be the dominant sorption mode indicated by non-linear isotherm data for PS. However, the results emphasize that neither sorbate nor sorbent-specific parameters sufficiently explain the observed difference in sorption alone.

128
Chemical Adsorption of Hydrophobic Polycyclic Aromatic Hydrocarbons in the Marine Environment onto Microplastic Polymers and Subsequent

Desorption in a Simulated Gut

C.B. Crawford, University of the West of Scotland / Institute of Biomedical and Environmental Health Research; M. Russell, Marine Scotland Science / Marine Environmental Assessment; C. Ewins, B. Quinn, University of the West of Scotland / Institute of Biomedical and Environmental Health Research

With an approximate degradation time of 450 years, plastic is one of the most durable and persistent environmental contaminants in the modern world. Production since the 1950s has increased prodigiously. In the marine environment, photo-oxidative degradation and the abrasive action of waves progressively degrade larger pieces of plastic into tiny polymer particles less than 5 millimetres in diameter, termed microplastics. As a consequence of their small size, microplastics are inadvertently ingested by ocean dwelling biota, particularly susceptible filter feeders such as Mytilus edulis and many species of fish. This can result in detrimental effects such as inhibition of gastrointestinal function and feeding impairment. However, it has emerged fairly recently that microplastic polymers collected from the marine environment have been found to have Hydrophobic organic chemicals (HOCs), such as polycyclic aromatic hydrocarbons (PAHs), adsorbed onto their surface. Since marine organisms ingest microplastics, it can be proposed that microplastics have the potential to act as a transporter for the conveyance of hydrophobic persistent organic pollutants (POPs), such as PAHs, into marine biota. PAHs are formed from incomplete or inefficient combustion of organic material, diagenesis and biosynthesis. While there is a consistent background level from forest fires and volcanic activity, a significant fraction of PAHs present in the environment is due to anthropogenic activities, such as internal combustion engines. Consequently, PAHs reach the marine environment via sewage and industrial discharges, oil spillages and deposition from the atmosphere. One particular characteristic of PAHs is their susceptibility to ultra-violet light. However, pericondensed PAH structures are more centrally condensed allowing them to withstand higher ultraviolet fluxes. This results in a decrease in susceptibility to photodecomposition by ultraviolet light and thus, resistance to degradation in the marine environment. Consequently, microplastics can then adsorb these contaminants. Since many of the susceptible organisms that ingest microplastics are located at the bottom of the food chain, chemical adsorption provides a potential mechanism for the bioaccumulation of contaminants in marine organisms and the potential trophic transfer of these contaminants up the food web to larger organisms, and possibly humans. Consequently, it is necessary to investigate this potential mechanism. \n

129

Dioxin-like activity of compounds sorbed to 4 different plastic polymers deployed in the San Diego Bay area

C. Schoenlau, M. Larsson, M. Lam, Orebro University / MTM research center Department of Science and Technology; C.M. Rochman, UC Davis / Society of Conservation Biology; A. Kaerrman, SCHOOL OF SCIENCE AND TECHNOLOGY; M. Engwall, Orebro University / MTM research center Department of Science and Technology

In the early 1970s plastic particles were detected in the marine system for the first time and by the late 1990s over 180 species were reported to ingest plastic particles. The occurrence of plastic litter in the marine environment poses not only a physical threat to organisms via entanglement and ingestion, but also a toxicological threat to wildlife. In recent years it has been demonstrated that various anthropogenic environmental pollutants can be found on different types of marine plastic debris. Most of these substances are considered as harmful to humans and wildlife. They can act as mutagens, cancerogens and endocrine disruptors and exert adverse health effects to organisms. The toxicological potential of anthropogenic pollutants derived from marine plastic is a yet little studied research area. In this study virgin plastic pellets of four different polymer types, polypropylene (PP), polyvinylchloride (PVC), polyethylene terephthalate (PET), and low-density polyethylene (LDPE) were deployed for nine and twelve months in different sites of the San Diego Bay area. The plastic pellets were extracted using hexane and ultra-sonication. Extracts were analyzed for their dioxin-like activity in the H4IIE luc assay, a mechanism specific bioassay based on a recombinant receptor/reporter vertebrate cell line, and chemical analysis of 23 PAHs including the 16 priority PAHs listed by the U.S. EPA. Bio-TEQs$_{25}$ and Chem-TEQs$_{25}$ values were calculated. Among the different polymer types LDPE demonstrated the highest dioxin-like activity in the samples followed by PP, PVC and PET. The calculated Chem-Teq$_{25}$ values supported a higher toxicity potential for LDPE compared to the other polymers. Studies of time dependent sorption were hampered by too few sampling time points but a slightly higher PAH concentration after twelve months compared to nine months could be observed indicating continuing sorption capacity. In contrary, the biological activity decreased from nine to twelve months. This leads to the assumption that other compounds than the analyzed PAHs might show a desorption from the plastic between 9 and 12 months which results in a decreased activity in the bioassay. This study shows that virgin polymer pellets are able to sorb pollutants from ambient water that induces a dioxin-like effect and that LDPE has a higher sorption capacity for PAHs and other dioxin-like compounds that were not measured in this study compared to the other polymers.

130

Evaluation of the analysis of microplastics by mass spectrometry and assessment of their adsorption capacity for organic contaminants

m. llorca, Institute of Environmental Assessment and Water Research; G.F. Schirinzi; J. Sanchís, IDAEA-CSIC / Water and Soil Quality Research Group; D. Barcelo, IIQAB-CSIC / Dept Environmental Chemistry; M. Farre, IDAEA-CSIC

Plastic residues in the sea are an emerging environmental problem because of human activity. The presence of these marine debris particles in the ocean represents not only an aesthetic problem since they also can imply harmful damages for the coastal areas and the socioeconomic activities linked to these regions[1,2]. The low degradability of these plastics and their size hamper the oxygen exchange and light which lead to eutrofisation processes[2]. Among these marine debris, microplastics are risky for primary producers and their impact has not been fully evaluated [1]. Nonetheless, different studies revealed their ubiquitous presence in the sea as well as its uptake by marine biota[3]. MPs can enter into marine food web and, finally, into human diet. In addition, these MPs can accumulate persistent organic contaminants and pathogens being also an environmental distributor of these ones [1,4,5]. The main objectives of this work are the evaluation of different ionization sources coupled to mass spectrometry analyzers for the analysis of MPs (High Density Polyethylene, polystyrene and functionalized polystyrene-COOH) in water columns and; the evaluation of adsorption mechanisms of organic contaminants (*i.e.* polycyclic aromatic hydrocarbons (PAHs)) and emerging organic contaminants (*i.e.* perfluoroalkyl substances (PFASs)) onto MPs surface. The study of MPs by means of MALDI-TOF and APCI-QExactive allowed the chemical characterization as well as semi-quantitative analysis in the case of the last one. These technologies can be applied in the future for the analysis of environmental matrices such as water columns, sediments or biota. Regarding adsorption experiments under a controlled sea water conditions, the results evidenced that MPs can behave as carriers of the studied PAHs and PFASs in marine environments. The compounds are adsorbed onto MPs surface after short exposure time and these can act as carrier materials being an important contamination source of selected organic contaminants for marine flora and fauna. **Keywords:** microplastics, mass spectrometry, carrier materials of organic contaminants [1] Cole M. et al. 131

Characterisation, Quantity and Sorptive Properties of Microplastics Extracted From Cosmetics

I. Napper, A. Bakir, S.J. Rowland, Plymouth University; R.C. Thompson, Plymouth University / School of Marine Science and Engineering

Cosmetic products, such as facial scrubs, have been identified as potentially important primary sources of microplastics to the marine environment. To better understand the source, we characterised, quantified and then investigated the sorptive properties of plastic microbeads that are used as exfoliants in cosmetics. Polyethylene microbeads were extracted from several products, and shown to have a wide size range (mean diameters between 164 to 327 µm). We estimated that between 4594 – 94500 microbeads could be released in a single use. To examine the potential for microbeads to accumulate and transport chemicals they were exposed to a binary mixture of ^{3}H-phenanthrene and ^{14}C-DDT in seawater. The potential for transport of sorbed chemicals by microbeads was broadly similar to that of polythene (PE) particles used in previous sorption studies. In conclusion, cosmetic exfoliants are a potentially important, yet preventable source of microplastic contamination in the marine environment.

Cost effective and ecological relevant approaches in environmental toxicology using invertebrate species

132

Is Multixenobiotic Resistance System in Daphnia magna a general stress response mechanism?

B. Campos, IDAEA-CSIC / Environmental Chemistry; R. Jordão, CESAM & University of Aveiro / Biology; C. Rivetti, IDAEA-CSIC / Environmental Chemistry; H. Watanabe, Osaka University / Biotechnology; C. Barata, CSIC / Environmental Chemistry

Recent investigations show that the cellular multixenobiotic resistance (MXR) system represents a broad-scale defense mechanism protecting cells against environmental toxicants. The system is mediated by membrane transporter proteins which pump chemicals out of the cell, thus keeping their levels low. Organisms and cells with potent MXR defense are less sensitive to the toxic impact of compounds, because comparatively few of those molecules reach their site of toxic action. In a recent study this system was characterized in the crustacean *Daphnia magna*, sequencing four gene transporters that were constitutively expressed across live stages and induced by several chemical contaminants. Transporter activirty of this proteins were also characterized showing that inhibition of MXR-like efflux activity by MXR-inhibitors co-administered with toxic substrates of MXR enhanced the toxicity of the latter compounds. However, model ABC transporter substrates, inducers and inhibitors used did not allow distinguishing between ABCB and ABCC transporters activity types. Here, we present results of experiments designed to clarify the role of these transporters and its specificity. We selected tolerant clones by exposing outbreed populations to high concentrations of chemicals that are known to be substrates of MXR. Selected tolerant clones were then used to characterize MXR mechanisms. The response of heat shock proteins (Hsp70) was also studied to distinguish between substrate specific MXR responses from general stress. An ABCB knock-down gene clonal line was also developed taking advantage of the recent development of the CRISPR/Cas9 methodology in Daphnia. Results showed successful selection of tolerant clones relative to the lab clone by mitoxantrone, pentachlorophenol and ivermectin. Mitoxantrone and pentachlorophenol enhanced the transporter activity in their respective selected tolerant clones. However, high transcriptional levels of the abcb1 gene were only positively related with high transporter activity in the selected pentachlorophenol tolerant clone. All tolerant clones showed high constitutive levels of Hsp70 protein, which means that the selection of clones with enhanced levels of MXR may be part of a general stress response. In conclusion tolerant genotypes having higher levels of general stress and MXR proteins exist in natural populations of *D. magna* and can be selected by toxic compounds that are substrates of ABC transporters.

133

Functional characterization of hemocyte populations of zebra mussel, Dreissena polymorpha and use in acute ex vivo toxicity tests

L. Evariste, Université de Reims Champagne-Ardenne; D. RIOULT, UMRI 02 INERIS-URCA-ULH SEBIO / MOBICYTE flow cytometry core facility; S. Audonnet, Université de Reims Champagne Ardenne / URCACyt Plateau technique de cytométrie en flux; E. David, Université de Reims Champagne Ardenne / UFR Sciences Exactes et Naturelles; M. Auffret, Universite de Bretagne Occidentale / LEMAR; M. Fournier, INRS-Institut Armand Frappier / ISMERUQAR; S. Betoulle, URCA / UMRI SEBIO

The zebra mussel, *Dreissena polymorpha,* is an invasive freshwater bivalve mollusk native from Ponto-Caspian region that successfully colonized Western Europe and North-America. Because of its biological characteristics, transplanted or natural populations of zebra mussels were used as sentinel species in freshwater pollution monitoring and also in laboratory studies. Immune system constitutes a central point in organism homeostasis. This physiological process relies on hemocyte activities that are sensitive to chemical stress. Disturbance in immune response may affect mussels in their related populations. The first objective of this study was to characterize *D.polymorpha* hemocyte subpopulations under natural conditions. According to microscopy and flow cytometry analysis, three types of circulating hemocytes can be observed: hyalinocytes and blast-like cells for agranular hemocytes and one granulocyte population. Flow cytometry analysis of hemocytes functionalities indicated that blast-like cells possessed low activities and that hyalinocytes and granulocytes are fully equipped to perform innate immune response and exhibited close functionalities. The second objective of this study was to assess the cytotoxic effects of cadmium, a non-essential metal and persistent pollutant, on hemocyte subpopulations by involving a multi-marker approach. Hemocytes were exposed *ex vivo* to concentrations of cadmium ranging from 10^{-6}M to 10^{-3}M for 21 hours prior flow cytometric analysis of cellular markers. Measured parameters (viability, phagocytosis, oxidative activity, lysosomal content and mitochondrial activity) were affected in a dose-dependent manner. Analysis indicated different sensitivity to cadmium depending on cell endpoint and cell subtype. This work highlighted importance of hemocyte characterization for a better understanding of toxicological responses of invertebrates to xenobiotics.

134

Highly cost-efficient determination of efflux pump inhibition and chemosensitization using single embryos of the pond snail Lymnaea stagnalis

K. Pedersen, University of Southern Denmark / Department of Biology

Measurements of efflux pump activity in single embryoes of *Lymnaea stagnalis* was shown to be a highly cost-efficient alternative to systems using human cell cultures. Results for the inhibitory effects of a range of pharmaceuticals showed the same effects in the same concentration ranges as previously reported in cell culture experiments. Further, the system was shown to be able to distinguish different modes of inhibition as well as being able to conveniently show chemosensitizing effects of pharmaceuticals.

135

Time-course immunomarker assessments and life-history traits in the freshwater snail Lymnaea stagnalis in response to environmental contaminants

P. Boisseaux, Irstea Lyon / MAEP Laboratory of Ecotoxicology; P. Noury, Irstea Lyon; H. Thomas, University of La Rochelle / UMR LIENSs laboratory; J. Garric, Irstea Lyon / Ecotoxicological Laboratory

Animals are under constant **multistress** pressures (e.g. chemicals and microbes). Hence, their immune system may be affected by the presence of chemicals (i.e. immunotoxicity). As a result, internal defences are inoperant to remove the microbiological burdens with possible consequences at the population level. In ecotoxicology, development and comprehension of biological tools that evaluate the effects of chemicals onto the **immune system** of invertebrate species are required (Galloway and Depledge 2001). *Lymnaea stagnalis* is a freshwater **gastropod** ecologically representative of lentic systems from holarctic zones of the planete. This species has been promotted in OECD guidelines for reprotoxicity testings (Ducrot 2014). It has the particularity to extrude a sufficient quantity of hemolymph that allows an **individual approach** (i.e. not pooled) of immunomarkers assessment in an **non invasive** manner, which also means that a **time-course evaluation** can be realized withtout animal sacrifice. Plus, hemolymph can be collected easily only by using a micropipette. Gust et al. (2013) reported immunotoxicity of contaminated surface waters toward *L. stagnalis*. More investigation remains essential in order to understand the feasability of using markers of immunotoxicity from *L. stagnalis*. Herein we investigated the time-course evolution of individual snails **hemocyte biomarkers** (i.e. density, viability, oxidative activity, phenol-oxidase activity and activity of phagocytosis) under contamination contexts. Simutaneously, an evaluation of **life-history traits** was carried out (i.e. survival, reproduction and feeding behavior). **The pyrethrinoid Deltamethrin** was set up in a flow-through system. The **Cadmium chlorure** ($CdCl_2$) was set up in semi-static conditions. Hemocyte biomarkers were evaluated by flow cytometry (densities, viabilities and activity of phagocytosis) and by spectrofluorimetry (phenol-oxidase and NADPH-oxidative activities). Reproduction was followed by collection of egg-masses and observation under binocular microscope. We observed that phenomenons of immunotoxicity may be transient (i.e. biological recovery) and so the time-course tracking of individual parameters is important. The comprehension of hemocyte biomarker variability is mandatory : inter-populations, intrapopulation (i.e. inter-individual) and intra-individual (i.e. time effect, physiological fluctuations). Thus, *L. stagnalis* deserves more attention as model organism in immunotoxicology.

Nickel toxicity to tropical marine biota

F. Gissi, CSIRO Oceans and Atmosphere / CSIRO Oceans and Atmosphere; J. Stauber, CSIRO / CSIRO Land and Water; D.F. Jolley, University of Wollongong / School of Chemistry; M. Binet, CSIRO / CSIRO Land and Water; M. Trenfield, Department of Environment Water Heritage the Arts; J. van Dam, Australian Institute of Marine Science; C.E. Schlekat, NiPERA; E.R. Garman, NiPERA / Ecotoxicologist

Over two-thirds of the world's nickel production is in tropical regions including Indonesia, the Philippines, Australia, New Caledonia, Brazil and Cuba. The mining, refining and smelting of lateritic ores can present many potential environmental risks, as with any such operations located in tropical regions of high ecological diversity. However, our current understanding of the toxicity of nickel to tropical biota is limited, largely due to the lack of ecotoxicity data with tropical species endemic to these regions. The Nickel Producers Environmental Research Association is currently leading a research program to develop and apply risk assessment tools to support the sustainable development of lateritic nickel deposits in the tropical region of South East Asia and Melanesia (SEAM). This research involves the compilation of exposure and effects assessment data for nickel in tropical marine waters, specifically in the SEAM region. Key gaps for ecologically important tropical taxa of the SEAM region include corals, crustaceans, gastropods, bivalves and fish. The aim of this study was to investigate the sensitivity of tropical marine biota to nickel, with a focus on those species relevant to the SEAM region. Data produced from this study will contribute to the development of a reliable and ecologically relevant water quality guideline value for nickel in tropical marine waters. Chronic nickel toxicity to two crustaceans (copepod and barnacle) and one gastropod (snail) native to the SEAM region was investigated. Toxicity tests were carried out at temperatures of 28-30 C and a salinity of 35‰. Endpoints measured included 72-h development (from egg to copepodite), 96-h metamorphosis and 96-h growth for the copepod, barnacle and snail, respectively. Throughout all tests, water quality parameters were monitored and sub-samples were taken to measure total and dissolved ($< 0.45\ \mu$m) nickel. The copepod was the most sensitive to nickel, followed by the barnacle and snail, with IC10 (10% inhibition concentration) values of 15, 72 and 79 μg Ni/L. This study provides valuable toxicity data which can be used in the development of an ecologically relevant guideline value for nickel in tropical marine waters.

Effects of multiple stressors on freshwater macroinvertebrates in Iberian rivers

M. Kuzmanovic, CSIC Spanish National Research Council; N. De Castro-Català, Universitat de Barcelona / Ecology; J. López-Doval, University of São Paulo / Depto de Ecologia Laboratorio de Limnologia; I. Muñoz, University of Barcelona / Ecology; A. Ginebreda, CSIC - Spanish National Research Council / Department of Enviromental Sciences; D. Barcelo, IIQAB-CSIC / Dept Environmental Chemistry

Aquatic ecosystems worldvide are impacted by a variety of stressors, including organic and inorganic pollution, excess input of nutrients, geomorphological alterations, land use changes, hydrological stress, invasive species and pathogens

[1]. As a consequence, the biodiversity decline is one of the greatest ecological problems nowadays [2]. However, little is known beyond the described effects of single stressors on specific ecological endpoints [3] and our understanding of the main causes for the losses of biodiversity still remains vague. Besides the usual taxonomy-based approaches, trait-based approaches are being increasingly used as an alternative to assess stream biological integrity and discriminate the influence of individual antropoghenic stressors and natural influences. Traits may help to reveal the cause of impairment and give an indirect insight into which ecosystem functions may be affected by human disturbance [4]. The objectives of this study were following: a) to assess the risk/presence of multiple stressors in four Iberian rivers and b) to test if we can observe the adverse effects of stressors in the local benthic macroinvertebrate communities c) to determine the difference of taxonomical and functional (traits) diversity changes in relation to stressors present and finally d) to discriminate which stressor or stressors are influencing more than others on the macroinvertebrates. The presence of one or more potential stressors was evident at all the sampling sites. The highest risk was mainly present at the lower parts of the rivers in the area surrounded by agricultural lands or/and urban zones where high concentrations of toxicants, in particularly insecticides, were found. Both organic micropollutants (particularly pesticides) and heavy metals significantly contribute to acute ecotoxicological risk. Besides, most of the sampling sites were characterized by combinations of two or more stressors; such as organic pollution, metals, high nutrient levels and conductivity.

Metals in the Environment: Fate, Speciation and Bioavailability in Water, Soil and Sediment (III)

138

A biophysicochemical approach for assessing the dynamics of metal biouptake and toxicity

E. Rotureau, CNRS UMR 7360 / Laboratoire interdisciplinaire des environnements continentaux LIEC CNRS UMR; P. Billard, R. Présent, LIEC Université de Lorraine CNRS; N. Paquet, M. Lavoie, C. Fortin, INRS Centre Eau Terre Environnement; J.F. Duval, CNRS / Laboratoire interdisciplinaire des environnements continentaux LIEC CNRS UMR

Understanding the toxic and essential trace compounds uptake by microorganisms under conditions relevant to natural environment is a major trigger of concern in environmental risk assessments. While toxicity assays are well documented in numerous studies where exposed ambient concentrations of metals are related to toxicology endpoints such as mortality or growth rate, predicting metal toxicity with clear account of the dynamic interplay between cell growth and metal biointerfacial partitioning is still very scarce. We recently proposed an integrative theory where metal transport, adsorption, excretion, internalisation and depletion processes are rigorously accounted for. In addition, the effects of key cell biophysicochemical features (*e.g.* electrostatics or presence/absence of cell surface layer such as EPS) on metal uptake and toxicity were highlighted. In this presentation, the theory is briefly presented together with supporting experimental data collected on bacteria and algae suspensions exposed to Cd(II) solutions. In both situations, it is shown how a critical examination of these data with help of theory can be valuable in deciphering the mechanisms governing the partitioning of metal at biointerfaces over time and accompanied toxicity effects. The theoretical formalism detailed in this presentation clearly highlights the intimate relationships among the metal partitioning dynamics at the cell−solution interphase, the biophysicochemical properties of that biointerphase, and the cell growth inhibition kinetics.

139

Toxicokinetic-toxicodynamic model to explain the decreased bioaccumulation but increased toxicity of Cu in an estuarine clam under higher salinities

W. Chen, Xiamen University / College of the Environment Ecology; Q. Tan, Xiamen University - College of the Environment & Ecology / College of the Environment Ecology

Although it is well recogized that salinity affects metal toxicity to estuarine organisms, to quantitatively simulate and predict the effects of salinity is still a challenge. Salinity affects metal toxicity not only through water chemistry, but also by altering the physiology of organisms. The biotic ligand model (BLM), which can only consider the effects of water chemistry, is probabaly not applicable to estuarine waters. Indeed, in this study, we found that higher salinities led to lower Cu bioaccumulation in the euryhaline clam *Potamocorbula laevis*; however, the associated toxicity was not lower but higher. The toxicokinetics of Cu were determined by using Cu-65 as a tracer at 7 salinities, i.e., 5, 8, 10, 15, 20, 25 and 30 psu. Cu toxicity tests were also conducted at these 7 salinities. A two-compartment toxicokinetic-toxicodynamic model was then developed to explain the decoupled effects of salinity on Cu bioaccumulation and toxicity. With the increase of salinity, the uptake rate constant of 65Cu decreased significantly from 0.546 L/g/h to 0.213 L/g/h. The inhibitive effects of salinity on Cu bioaccumulation was consistent with the prediction of the BLM. Elevating salinity from 5 psu to 30 psu significantly raised the killing rate of Cu from 0.60 mg/μg/h to 2.08 mg/μg/h, while did not significantly affect the internal toxic threshold of Cu. This indicated that the excessively accumulated Cu manifested higher toxic effects to the clams at higher salinities, probably due to their higher osmoregulatory stress. Using the toxicokinetic-toxicodynamic model, we can quantitatively predict the effects of salinity on both Cu bioaccumulation and toxicity. This model can serve as a useful tool for assessing ecological risks of Cu in estuary waters. **Key words:** salinity, copper, toxicokinetic-toxicodynamic model

140

Behavior and toxicity of silver nanoparticles and silver nitrate in aquatic indoor microcosms

C. Wasmuth, C. Schäfers, Fraunhofer IME - Institute for Molecular Biology and Applied Ecology; H. Ruedel, Fraunhofer IME - Institute for Molecular Biology and Applied Ecology / Environmental Monitoring

In this study effects of AgNPs and $AgNO_3$ are investigated to assess toxic effects of AgNPs and Ag^+. Therefore the release of Ag^+ from AgNPs and $AgNO_3$ and the accessibility of Ag^+ in the water phase is researched in separated microcosms with a volume of 1 m^3. The microcosms contain natural sediment (0.25 m^3), surface water (0.75 m^3), zooplankton and phytoplankton. AgNPs with a mean diameter of 20 nm and $AgNO_3$ were applied into aquatic indoor microcosms at four different target concentrations, respectively. In addition four control microcosms were used. During a period of 100 days target concentrations were maintained by regular test item additions. The recovery was followed over additional 150 days. To allow observation of toxic effects, data of cell density were collected. The aim of this near-to-nature approach is to give an as precise as possible picture of nanoparticle behavior and toxicity on aquatic communities and to enable a direct comparison to effects caused by $AgNO_3$. 78 days after start of the exposure, maximum concentrations of Ag^+ were observed for both AgNPs and $AgNO_3$test systems. Independently from the initial AgNP loading no higher concentration of Ag^+ could be measured in the water phase. At the current point of the study evaluation results of cell density measurements indicate a phytoplankton growth in AgNP treated microcosms and a potential degradation of zooplankton. The exposure to 5 μg/L AgNPs lead to an exponential growth of phytoplankton until day 42. This effect seemed to be induced by a degradation of zooplankton. The application of lower AgNP concentrations (0.078, 0.313 and 1.25 μg/L) did not lead to changes of the amount of cells in the water phase. This may indicate that the zooplankton is not directly affected by exposure to AgNPs. Nevertheless, after stopping the test item additions similar amounts of cells could be found in the water phase of all treated microcosms and controls. Apparently similar communities were present in all microcosms and the recovery of the communities occurred in spite of the presence of remaining silver in the system.

141

Arsenic induces changes in gut microbiota associated to mucus in vitro models

M. Calatayud, Laboratory of Microbial Ecology and Technology; W. Ossieur, Ghent University / Center for Microbial Ecology and Technology; T. Van de Wiele, Ghent University / Laboratory Microbial Ecology and Technology

Arsenic (As) is an environmental contaminant widely distributed through the Earth crust. The main route of exposure to inorganic arsenic, the most toxic arsenical specie in contaminated water and food, is via oral. Arsenic absorption occurs mainly in the small intestine, however non-absorbed arsenic can reach distal gastrointestinal regions. Human trials showed that 44-60% of arsenic ingested after rice consumption was excreted through urine in five days, so the remaining amount of As could reach colon or be retained in the human body [1]. Therefore the colonic absorption of arsenic can contribute to As internal exposure and, moreover, arsenic could interact with distal gut microbial community. Gut microbiome, therefore, should be considered as an environmental factor affected and, also, influencing arsenic toxicity. This research evaluated in vitro the effect of environmentally relevant doses in mucus associated gut microbiome using batch assays and the simulator of the human intestinal microbial ecosystem (SHIME), including the mucus environment (mucus-SHIME, M-SHIME). Faecal samples from healthy individuals were inoculated in batch assays and M-SHIME reactor and exposed to arsenic (10 and 100 μg/l). After different time points, the metabolic activity of the gut microbiota was assessed by quantifying short chain fatty acids, branched short chain fatty acids and ammonium contents. Structural changes on mucosal microbial community was performed by polymerase chain reaction (PCR)-denaturing gradient gel electrophoresis (DGGE) of the 16S ribosomal RNA (rRNA) gene and quantification of 16S rRNA gene copy numbers by real-time PCR (qPCR). The results obtained show that arsenic exposure affected significantly the branched short chain fatty production in fed batch and M-SHIME experiments, indicating changes in the metabolic activity of gut microbiome related with the protein metabolism.The DGGE fingerprint of total bacteria in alginate mucus beads was significantly affected after arsenic exposure after processing gel bands with Bionumerics software. The results presented in this work suggest that the gut microbiome is an environmental factor to consider in risk assessment of arsenic exposure. The health consequences of arsenic interaction with gut microbiota need further research. The mucus associated bacteria are suggested as a key element in the arsenic – host interplay.

Copper-induced changes in intracellular thiols in marine algae

D.F. Jolley, C. Smith, University of Wollongong / School of Chemistry; J. Stauber, CSIRO / CSIRO Land and Water

Toxicity of metals to aquatic organisms is dependent on both external factors, such as exposure concentration and water quality parameters, and intracellular processes including specific metal-binding sites and detoxification. Current models used to predict copper (Cu) toxicity in microalgae do not effectively consider the intracellular processes. This research examined the toxicity of Cu towards microalgae by investigating the intracellular Cu-binding ligands of phytochelatins and glutathione from four species of marine microalgae exposed to Cu at their respective IC_{50} (concentration of Cu required to inhibit population growth by 50 %) at intervals over 72-h. IC_{50} values were chosen to represent equal amounts of cellular stress across the four species despite their differences in Cu tolerance. Despite similar Cu tolerances in *Phaeodactylum tricornutum* and *Ceratoneis closterium*, differences in internalised Cu, phytochelatin production and reduced glutathione were observed. *P. tricornutum* maintained reduced glutathione at 58 - 80% of total glutathione levels throughout, whereas in *C. closterium* reduced glutathione constituted < 10% of total glutathione after 48 h of Cu exposure. *P. tricornutum* internalising significantly less Cu but produced more phytochelatins and of longer chain length than *C. closterium*. Two green algae, *Dunaliella tertiolecta* and *Tetraselmis* sp. had very different Cu tolerances, and also exhibited differences in internalised Cu, phytochelatin production and reduced glutathione concentrations. *Tetraselmis* sp. internalised three times more Cu than *D. tertiolecta* and had significantly more intracellular thiols. In both green species a decrease in the reduced:oxidised glutathione ratio was observed following Cu exposure. Phytochelatin production was markedly different between acute (< 24 h) and chronic exposures (24 – 72 h), with shorter chain lengths dominating for chronic exposures. Reduced glutathione increased slightly at longer exposures in both species, potentially indicating a decrease in intracellular oxidative stress despite a consistent increase in intracellular Cu. This work has shown that the intracellular reaction to Cu is species specific, and responses were not necessarily related to their respective tolerances, or the amount of intracellular Cu. This suggests that there may be multiple modes of Cu toxicity and that detoxification processes vary between species.

143
Time-course metabolomics responses of transplanted oysters Crassostrea hongkongensis to estuarine metal pollution

C. CAO, Hong Kong University Sci. Technol.; W. Wang, Hong Kong University Sci. Technol. / DIVISION OF LIFE SCIENCE

In a dynamic and fluctuated estuarine environment, heavy metal toxicity is greatly influenced by various environmental stressors, increasing complexity and difficulty of accurately predicting potential biological/ecotoxicological effects simply based on indoor laboratory experiments. In this research, metabolomics responses of oysters *Crassostrea hongkongensis* were characterized under metal contamination in an estuary. Oysters were transplanted from a clean site to multiple-metal-contaminated sites in an estuary for six months. Both metal concentration and metabolomics responses in oysters' digestive glands were investigated over different periods of exposure (0 week, two weeks, four weeks, and six months). Following transplantation, all metals (Ni, Cr, Pb, Cd, Cu and Zn) in digestive gland tissues showed an elevated trend over time. Cu, Zn and Cd were dominant polluted metals. Using ^{1}H NMR metabolite approach, we demonstrated that significantly varied metabolites were mainly responsible for osmotic regulation, energy metabolism, nucleotides and glycerophospholipid metabolism. Within initial four weeks of exposure, the amount of amino acids and osmolytes was increased for osmotic regulation. Addtionally, energy demand was decreased to accumulate glucose and glycogen for adaptation. However, oysters mobilized early accumulated amino acids and energy storage compounds to produce ATP and maintain a normal physiological function over a longer period of exposure. The metabolomics study demonstrates that oysters adopt different strategies to maintain living status in a heavily-metal-contaminated environment.

Modelling of pesticides and biocides fate and exposure in a regulatory context

144
Impact of updated modelling methodologies on pesticide E-fate risk assessments

A. Boivin, ANSES

Regulation 1107/2009 states that active substances used in plant protection products are only approved in the EU if it may be expected that their use will not have any harmful effects on human and animal health or the environment. In practice, risk assessment is performed for the active substance (at European level) and for the product containing the active substance by EU member states (in the context of the Zonal procedure). While regulation may provide indications on the data requirement and the protection goals, procedure on how to derive predicted environmental concentrations in the different compartments is made in guidance documents publicly available. Such guidances are valuable in order to improve the risk assessment methodologies. It's also noticeable that guidances are also updated or complete with aim to achieve a high scientific quality in the risk assessment. In addition they may help to harmonize the risk assessment carried out for pesticides at EU and zonal level. In the environmental fate and behaviour area, at least 9 guidances are available covering the various compartments, process and crop type. Anses proposes some feedbacks of guidance implementation and the practical or foreseen consequences on risk assessment. It includes worked examples to identify sensitive topics highlighted during risk assessment performed by member states. Consequences for the environmental fate and behaviour (and ecotoxicology) sections and the associated risk assessment are discussed. Benefits and drawbacks are discussed.

145
Can the Danish regulatory modelling approach assess the leaching risk of pesticides and their metabolites as monitored via the Danish Pesticide Leaching Assessment Programme?

S. Pullan, TSGE Consulting; A. Gimsing, The Danish Environmental Protection Agency / Pesticides and Gentechnology; P.R. Branford, TSGE Consulting / Environmental Sciences; A.E. Rosenbom, Geological Survey of Denmark and Greenland

The regulation of pesticide use in Denmark is based on the European Union (EU) registration processand guidance documents for the Northern Zone and Denmark. As described in these guidance documents, the Danish assessment of the risk of leaching of pesticides to groundwater is based on modelling with the FOCUS Hamburg model scenario (PELMO) or the two national model scenarios Karup and Langvad (MACRO). The approach taken by Denmark also differs from that of the EU with respect to consideration of relevancy of metabolites, selection of degradation rate and sorption parameters and the evaluation of predicted environmental concentrations in groundwater. In Denmark, if modelling indicates leaching below, but close to the threshold of 0.1 $\mu g\ L^{-1}$, the compound's leachability may be evaluated in the Pesticide Leaching Assessment Program (PLAP). PLAP is an intensive monitoring programme evaluating the risk of leaching of pesticides and/or their metabolites under field conditions. PLAP today encompasses five fields representing various types of soils and near surface geology where the pesticides are used at a realistic worst case dose and according to good agricultural practice. The PLAP-fields have been thoroughly characterized (e.g. pedology, hydrogeology) and monitored as regard to the water balance. Modelling was carried out according to the Danish and EU approach for 27 pesticides and 19 metabolites that have been tested in PLAP. The modelling results were compared to the findings in the groundwater wells in PLAP. As expected there are differences between the Danish and the standard EU approach with regard to the modelling results. Due to the more conservative input and more conservative approach for interpreting output, the results for the Danish approach generally predicts a greater risk of leaching. Comparison with the results for PLAP reveal that in some cases the models over-estimate the leaching risk. The potential causes for this discrepancy between simulated and observed leaching scenarios will be explored. **\n**

146
Drainage models and macroporous soils

E. Van den Berg, Environmental Risk Assessment Team; N. Jarvis, SLU / Soil and environment; K. Hammel, Bayer CropScience Aktiengesellschaft; B. Gottesbueren, BASF SE / Crop Protection; A. Poot, Ctgb

In the procedure for the registration of plant protection products at the EU level and at the member state level, simulation models are used to assess the fate of these products in the soil. Preferential flow is an important process which can significantly affect the leaching of plant protection products through soil and discharge via drains into surface waters. A scientific SETAC Workshop was organised in Vienna, Austria, from 23 to 24 October 2014 on drainage models and macroporous soils. Scientists that are actively involved in research on the fate of plant protection products in macroporous soils were invited to participate. In addition, representatives from industry, registration authorities and consultancies were also invited. The focus of the workshop was on the validation status of models that are available at present for the description of the fate of plant protection products in macroporous soils and to make recommendations for improvement of model concepts for macropore flow in soils as well as to elaborate the data requirements needed to test the improved model concepts. The models that were considered in detail were HYDRUS, MACRO and SWAP/PEARL. In key note presentations the state of the art in this research domain was presented. The workshop consisted of plenary sessions, in which participants were given the opportunity to give a short presentation on the topics to be addressed in the session and break-out sessions to discuss specific subtopics. The differences in conceptual approaches, options to consider dual permeability and dual porosity systems, equilibrium and non-equilibrium domains and options for bottom boundary conditions in the HYDRUS, MACRO and SWAP/PEARL models were discussed. Important fields that need further attention are the contribution of biopores to preferential flow. Further, the current description of surface processes in the models requires further attention, including the temporal variation of soil properties, which govern the infiltration of water. Tillage and traffic effects on macroporosity are currently not considered in the modelling, so concepts need to be developed that describe these processes in a realistic way. Further, more efforts are needed to test the improved models and as well as on elaborating the type of measurements needed to test these models in the field.

147
Options to consider during accumulation calculations for predicted environmental concentrations in sediment
D. Patterson, Syngenta; B. Erzgraeber, BASF SE; K. Hammel, Bayer CropScience Aktiengesellschaft
Predicted environmental concentration in sediment (PECsed) for regulatory purposes is currently calculated according to the FOCUS surface water report. The standard time frame of a FOCUS surface water simulation (12-16 months) could potentially limit the estimation of chemical accumulation in sediment. TOXSWA, however, is not currently parameterised to run over longer periods within current the regulatory framework. In this work we aim to identify the main processes which drive accumulation in the sediment and to discuss options to consider during accumulation calculations for regulatory exposure assessments. We considered a slowly degrading sorbative compound applied annually to winter wheat. The FOCUS surface water run-off scenerios were used to calculate the PECsed for one year and for 20 years. A second analysis was performed to examine sediment burial within run-off scenarios for annual application to winter wheat.Soil mass input and sediment chemical mass over 20 years were generated using SWASH. A simple, conservative assumption was made that 100% of the soil adsorbed chemical and erroded soil mass is deposited to the sediment along with partitioning to and from the water column. Applying the stratigraphic principle of superposition a stratigraphic column spanning 20 years was constructed. Both the stream and pond scenarios demonstrate that dissipation in the sediment compartment is dominated by desorption/back-diffusion. Neglecting dissipation by desorption and back-diffusion leads to overestimation of PECsed by a factor of 2.5 to 4. In the second analysis the constructed stratigraphic column demonstrates that in some cases >20cm of sediment would be deposited during a 20 year simulation. Furthermore, chemical mass would be distributed heterogenously throughout this deposited thickness and not solely within an upper 5 cm or 1 cm compartment. Neglecting the processes decribed here leads to overestimation of the potential accumulation in the sediment. Desorption and back-diffusion as a major sediment dissipation process is already considered in the current exposure assessment scheme over a 12-16 month time period. It could and should be used to quantify accumulation over longer time periods more realistically. Additionally, when calculating PECsed over a longer period the option of simulating burial of sediment should be available as a more realistic, higher-tier option for calculating sediment PECs within a regulatory context.

148
Effect of long-term sorption kinetics of pesticides on their simulated leaching to groundwater
J. Boesten, Alterra / ERA team
Assessment of leaching to groundwater is an important aspect of the risk assessment of pesticides within the EU. The lower tiers of this assessment are based on calculations with simulation models. The first tier is commonly based on the assumption of equilibrium sorption based on batch adsorption studies with a typical equilibration time of 24 h. In the past decade, interest has increased to include long-term sorption kinetics (LTSK) as a higher tier. It is therefore interesting to assess the likely magnitude of the decrease in leaching concentrations due to inclusion of LTSK. Calculations were made with FOCUS_PEARLv4.4.4 for the FOCUS Okehampton groundwater scenario with an annual application of 1 kg/ha in winter wheat one day before emergence. This was done for a range of substances using regular grid of K_{OM} and *DegT50* values; the K_{OM} ranged from 15 to 210 L/kg and the *DegT50* from 5 to 70 d. The desorption rate coefficient k_d was 0.025 d^{-1} and the ratio of the non-equilibrium Freundlich coefficient divided by the equilibrium Freundlich coefficient (f_{NE}) was 0.5. The Freundlich exponent N was set at either 0.7 or 0.9. There is a complication with respect to the parameterisation of the *DegT50* because the overall degradation rate is a function of $k_d$and f_{NE}. So if the effect of $k_d$and f_{NE} on leaching is studied while keeping the same *DegT50*, this would lead to comparing leaching of substances with different overall degradation rates which is not meaningful. This problem was overcome by simulating for each substance the decline of the mass of substance in a hypothetical laboratory degradation rate study with the Okehampton top soil at field capacity and 20°C and by deriving the first-order overall degradation half-life of this substance from a fit to these simulated data. Both for $N = 0.7$ and $N = 0.9$, for the vast majority of the *DegT50*-K_{OM} combinations the effect of including LTSK was closely related to the level of the leaching concentration: the lower the leaching concentration of the substance, the higher the effect of including LTSK. The effect of including LTSK was found to be considerably larger for $N = 0.7$ than for $N = 0.9$: for $N = 0.9$, a leaching concentration of 0.1 μg/L with LTSK corresponded with a concentration of about 1 μg/L without LTSK whereas for $N = 0.7$, 0.1 μg/L with LTSK corresponded with 3-8 μg/L without LTSK. \n

149
The EFSA PPR Statement on the FERA Proposal for Aged Sorption Guidance
A. Tiktak, Water Agriculture and Food; E. Capri, Universitá Catolica del Sacre Cuore; O. Jacobsen, GEUS; R. Kasteel, Agroscope; M. Klein, Fraunhofer IME; T. Van der Linden, RIVM / ENVIRONMENTAL QUALITY; A. Piccolo, University of Naples Federico II; M. Stemmer, Austrian Agency for Health and Food Safety / Institute for Plant Protection Products; M. Egsmose, EFSA
Aged sorption (also referred to as non-equilibrium sorption) refers to the increase of sorption of a substance over time. Although aged sorption is a generally accepted scientific phenomenon, the procedures to derive parameters of the aged sorption process are uncertain. The interest in aged sorption led to the inclusion of recommendations relating to the use of aged sorption parameters in the revised FOCUS groundwater report. However, the extent of investigation into this subject was limited and a general recommendation was made that default parameters for aged sorption could be adopted at higher risk assessment tiers for any substance. Separate experiences with the difficulties in considering aged sorption data in regulatory risk assessment triggered the UK Chemicals Regulation Directorate (CRD) to charge FERA (the Food and Environment Research Agency) with the development of guidance on study conduct and generation of aged sorption parameters suitable for use in regulatory risk assessment. The scientific Panel on Plant Protection Products and their residues (PPR Panel) was asked to prepare a scientific opinion on the FERA guidance proposal. The experimental and modelling approaches in the proposed guidance are reasonable compromises between the required effort and what is desirable from a theoretical point of view. The Panel has, however, concerns about the interpretation of the experiments and how results of the experiments should be used in the leaching assessment. The Panel investigated options for improvement. Evaluation will be finalised after the guidance document has been revisited by the authors..

Prospective and retrospective soil risk assessment of chemical stressors

150
Utility of a site specific soil microbial health assessment test suite to assess the impact of single chemicals on soil microorganisms for risk assessment
L. Beaudette, Environment Canada / Ecotoxicology and Wildlife Health Division; A.D. Samarajeewa, A. Crossman, Environment Canada; S. Kvas, Environment Canada / Biological Methods; R. Scroggins, Environment Canada
Soil microorganisms are an integral part of the terrestrial ecosystem playing a significant role in nutrient cycling and organic matter decomposition. As such, impairment of the soil microbial function and diversity, due to a contamination event, can lead to impacts at higher trophic levels over a period of time. To assess the impacts of soil contaminants on soil microbial function and diversity, Environment Canada (EC) developed a site specific soil microbial test suite. The test suite evaluates soil microbial biomass, activity, and community structure using the following tests: heterotrophic plate count, fumigation-extraction, nitrification, organic matter decomposition, substrate-induced respiration, basal respiration, bait lamina, enzyme assays, community level physiological profiling, and next generation DNA sequencing. Initially, the test suite was used to determine the impacts of site specific boreal forest contamination events (polycyclic aromatic hydrocarbon, metals) on the soil microbial community; however, until recently, the utility of the test suite has been realized for laboratory risk assessment research. Data will be presented on the use of the microbial test suite on healthy sandy loam reference soil spiked with different concentrations of chemicals. In contrast to the site specific results where EC50 values are not possible to calculate, risk assessment EC50 results will be presented to inform risk assessors of the impact of the chemicals on the soil microbial community.

151
Topical Scientific Workshop on Soil Risk Assessment (Helsinki, October 2015); problem definition and conceptual model
A. Kapanen, European Chemicals Agency - ECHA; K. Romijn, Bayer CropScience AG; J.H. Cermak, Environment Canada / Department of Biology; M.S. Greenberg, US EPA / Environmental Response Team; J. Tarazona, European Food Safety Authority / Pesticides Unit
Multidisciplinary and international collaboration is essential for developing a science-based methodology for risk assessment of chemicals released to or reaching soil. Topical Scientific Workshop on Soil Risk Assessment brought over 200 experts representing industry, academia, regulators and other stakeholders from all over Europe and across the world in order to discuss the state of the art in assessing the impact of industrial chemicals, biocides and plant protection products in soil. The overall aim was to identify the most critical improvement needs for soil risk assessment, and to identify in which cases the harmonisation of different regulatory approaches would bring an added value. Three main topics were discussed during the two-day workshop: Problem definition and conceptual model for soil risk assessment, Environmental exposure and fate assessment, and Effect assessment. Several areas where identified were harmonisation of the approached in scientific assessments for pesticides, biocides and industrial chemicals under REACH and international collaboration would bring added value for the soil risk assessment. This presentation will focus on the conclusions reached in discussion on the problem definition and conceptual model for soil risk

assessment and describe identified developments needs within regulatory framework. Following conclusions and development needs will be elaborated; It was seen as beneficial if technical development of specific protection goals (SPG's) could be harmonised across the industries and regions, if and where applicable, with clear definition of land/soil use, product use, exposure scenario and time scale. Ecosystem services approach was considered as useful communication tool in defining what do we want to protect. Considering bioavailability in soil risk assessment and defining concept of biodiversity (including functional biodiversity) in regulatory context. Combining exposure assessment – how the chemicals enter into and behave in the soil – with effect assessment – how the chemicals then affect different organisms. Additionally, other identified regulatory science-oriented R&D needs such as the application of the equilibrium partitioning method, a screening level for soil risk assessment, using information from aquatic organisms, and a calibration based on information on higher-tier studies will be discussed in more detail.

152

Translation of Ecosystem Services based Protection Goals into an appropriately calibrated tiered Collembola risk assessment of plant protection products - case study: lindane

G. Ernst, Bayer CropScience AG / Ecotoxicology; J. Bendall, Dow Agrosciences; M. Coulson, Syngenta; S. Loutseti, DuPont De Nemour Hellas S.A.; A. Sharples, Cheminova A/S; P. Kabouw, BASF SE

Soils provide relevant Ecosystem Services (EsS) e.g. by regulating water and nutrient cycles which have a direct impact on the EsS food production. In agricultural landscapes the biodiversity and the fertility of soils have to be protected from an unacceptable impact from PPP. However, landscapes are heterogeneous and different ecosystem services are provided by different parts of the landscape. Thus, a spatial differentiation needs to be taken into account when setting protection goals. Due to conflicting needs of different EsS it is not possible to protect biodiversity in all areas and all the time. Therefore, biodiversity should be protected on landscape level. Thus, the risk assessment should differentiate between 1) an off-field risk assessment where the focus is on protection of biodiversity and 2) an in-field risk assessment which should focus on protection of those soil functions which are directly related to the most relevant EsS for agricultural areas (i.e. food production). In order to improve the current toolbox for soil functional test systems that could be used in an in-field soil risk assessment a project was initiated by the European Crop Protection Association in 2014. Different functional test systems (litterbag test, minicontainer test, bait lamina test) are tested on their sensitivity to different insecticides in a field trial and evaluated with regard to their relevance for the EsS provided by soils, their degree and potential for standardization, and their suitability for being used in the risk assessment. The case study is focusing on one specific group of soil organisms (Collembola) and the ecosystem services they provide by examining different structural and functional tests in a tiered risk assessment approach. Laboratory tier 1 test will be compared with an intermediate tiered two-generation test, and higher tier field effect data on both a structural and functional level. We want to discuss how protection goals derived from the Ecosystem Services approach translate into an appropriately calibrated tiered risk assessment approach for collembola.

153

Topical Scientific Workshop on Soil Risk Assessment (Helsinki, October 2015): environmental fate and exposure assessment

R. Cesnaitis, European Chemicals Agency; W. Peijnenburg, RIVM / Center for Safety of Substances and Products; M. Egsmose, EFSA; C. Ajao, J.R. Peltola-Thies, ECHA-European Chemicals Agency; J. Tarazona, European Food Safety Authority / Pesticides Unit; A. Kapanen, European Chemicals Agency - ECHA

The main principles and elements of exposure assessment of chemicals in the soil are known and used accross various legislations. However some of the properties and processes should gather more consideration in the exposure assessment than is currently the case. Specific attention should be given to the substances possessing specific structures (e.g. structures that earmark a substance as PBT) or physico-chemical properties. The lack of realism in the fate testing requested under current regulatory frameworks, leads to the difficulties when the testing data are employed for the simulation of processes under real environmental conditions. In the workshop it was advised that the link between fate and exposure assessment on the one hand and hazard assessment on the other hand should be further improved. It was concluded that the bioavailability of the chemicals should be further understood and implemented in the regulatory framework. The possible harmonisation of the approaches and models used today for the soil exposure assessment was discussed by the participants of the workshop. The use of modelling tools for the exposure assessment and risk assessment in general has a great potential for further development and practical use, but the limitations in the use of available/newly developed tools needs to be well understood. The sharing of experiences and harmonisation of approaches for the fate and exposure assessments within different legislations was seen as a key possiblity for further improvement of the relevance and reliability of the soil risk assessments. Discussions on NER formation and bioavailability resulted in the conclusion that the topic has potential for the implementation into regulatory exposure assessment schemes. However, some concerns around the topic were raised. It was concluded that higher realism of the fate/exposure assessment (regardless whether it is based on laboratory/field measured or modelled data) and its linking with results of hazard assessment is necessary. There were specific proposals for initiating activities for the development of more realistic approaches/methods for soil exposure assessment taking into account additional parameters (physico-chemical) of substances and of the medium (soil) as well as integrating into the assessment methodologies other processes (e.g. desorption) and conditions relevant for the real environment. Research needs and the directions for development of the regulatory science were identified.

154

Validation of a New Environment Canada Test Method for Measuring Contaminant Effects on Survival and Reproduction of Soil Mites using Oppia nitens

R.P. Scroggins, Environment Canada / Biological Methods; J. Princz, H. Lemieux, R. Hennessy, Environment Canada / Biological Assessment and Standarization Section

In 1995, Environment Canada (EC) initiated a multi-year program to develop biological test methods that could be used to assess the toxicity of contaminants in soils using terrestrial organisms. The goal was to develop test methods that were applicable to Canadian soil types using species that were representative of Canadian soil ecosystems. The creation of a new Environment Canada test method for measuring survival and reproduction effects in contaminated soil using an oribatid mite is the latest soil testing methodlogy to be developed into a national standardized method. The principal procedure is a definitive 28-day test measuring chronic toxicity using adult survival and number of live juveniles as endpoints. The mite species recommended as the test organism of choise is *Oppia nitens* (C.L. Koch, 1839), a species found in surface soils across Canada. This toxicity test is based on EC research conducted by staff of the Soil Toxicology Laboratory. An inter-laboratory validation study will be initiated in January 2016 as part of the EC method standardization process. Eleven ecotoxicology laboratories from across Canada and Europe have volunteered to participate in this method ring testing effort. Participating laboratories have been establishing their *O. nitens* cultures for the past three months following standard operating procedures developed by EC. Three rounds of testing are planned for this method validation project which is schedule to begin in late January 2016. As a parallel effort, Environment Canada has begun formal method writing with the goal of having a 1st draft of the official test method completed before completion of the ring testing program. An overview of the test method and early results of the inter-laboratory testing program will be presented.

155

Outcome of the Topical Scientific Workshop on Soil Risk Assessment (Helsinki, October 2015): state-of-the-art and new developments in soil effect testing

J. Roembke, ECT Oekotoxikologie GmbH; K. van Gestel, VU University Amsterdam / Ecological Science; A. Kapanen, European Chemicals Agency - ECHA; V. Poulsen, ANSES / French Agency for Food Environmental and Occupational Health and Safety; J.F. Sousa, University of Coimbra / Dept Life Sciences of University of Coimbra; M. Sobanska, European Chemical Agency - ECHA; A. Catarino, Heriot-Watt University / School of Life Sciences; J. Tarazona, European Food Safety Authority / Pesticides Unit

The primary objective of this workshop was to review the state of the art regarding soil risk assessment in view of developing updated scientifically-sound principles and approaches for assessing ecological risks of chemical substances, which are released to or reach the soil. The workshop also provided a platform for academia, regulators and other stakeholders to address how the main long-term challenges from the regulatory perspective can be reflected and employed in the current and future research topics on soil risk assessment. The discussions were reinforced by information on the recent scientific developments and on risk assessment methodologies applied in chemicals management both within and outside the European Union. There was a common understanding that the Ecosystem Services (ES) approach can be a suitable conceptual framework to define specific protection goals in order to ensure the protection of the environment including biodiversity. This process encompasses the identification of ES provided by the soil system and associated species or communities responsible for the provision of these services (SPUs) through a dialogue with risk managers. Afterwards, a process for setting reference tiers (allowing direct comparison with the protection goals) and to calibrate down for intermediate and lower tiers, is needed. Particularly for the lower tiers, it has to be checked whether standardized test methods with those relevant species (SPUs) are available. If not, alternative test species and test methods have to be identified. Very few standard higher-tier tests are available. Finally, a list of recommendations was prepared by the workshop participants, providing ideas on how to proceed regarding soil effect test methodology in the light of the new risk assessment approach. During the workshop already several topics were identified where harmonisation of the approaches and international collaboration would bring added value for the soil risk assessment such as, just to mention a few, defining specific protection goals,

considering bioavailability in soil risk assessment and defining the concept of soil biodiversity in the regulatory context. In addition, already concrete proposals were made about launching activities on defining boundaries for applicability of the Equilibrium Partition Method approach, considering non-extractable residues, application of Species Sensitivity Distributions (SSDs) and revisiting assessment factors (AFs).

Life Cycle Data and Modeling Developments - From Data Collection to Usage (III)

156
A model and tool to calculate life cycle inventories of chemicals discharged down the drain
I. Muñoz, 2.-0 LCA consultants; N. Otte, Henkel AG   Co KGaA; G. Van Hoof, Procter & Gamble Services / Environmental Stewardship Organizatino; G. Rigarlsford, Unilever RD Colworth
A new model and tool to calculate life cycle inventories (LCIs) of chemicals discharged down the drain is presented. Its main innovation is the fact that it attributes the exchanges with the technosphere and the environment taking into account the expected behaviour of individual chemicals in the wastewater treatment plant (WWTP) and the environment, thus contributing to better decision making and data availability in the context of the life cycle of chemicals. The model covers treatment of organic and inorganic chemicals and input variables by the user include chemical-specific data (composition, phys-chem properties, half-lives, and fate factors in the WWTP) as well as scenario variables (% population connected to WWTP, country, nutrient removal in the WWTP, sludge disposal scenario including landfill, incineration and agriculture). The WWTP is modelled with a mass and energy balance taking into account the partitioning of the chemical to air, sludge, treated effluent, and depending on its degradability, the transformation by microorganisms to CO_2 and new biomass (excess sludge). Sludge is treated by means of anaerobic digestion and the fate of any fraction of chemical released to the environment (e.g. treated effluent, direct discharges) is assessed with a previously developed model, which calculates greenhouse-gas (GHG) emissions following degradation in environmental compartments. Besides GHG emissions, emissions of nutrients (N, P) are also considered. Concerning sludge disposal by incineration and landfilling, this is assessed by means of the models developed for the ecoinvent database, whereas reuse of sludge in agriculture is accounted for by means of tier 1 emission factors from the IPCC. The model is programmed in an Excel spreadsheet, the WW LCI tool, which accommodates simultaneous calculations for 30 chemicals, either individually or as a mixture. The output of the WW LCI tool is a comprehensive LCI linked to ecoinvent v3 data sets, that can be imported to LCA software in order to complement a life cycle assessment study of a particular chemical or a chemical mixture associated to a product or service. This model is the first one to address a chemical-specific and comprehensive LCI of chemicals discharged down the drain, including all the described processes. It constitutes an advance over previous models using generic descriptors like BOD, COD, etc. and constitutes an advance in how the end-of-life stage of chemicals is addressed in LCA.

157
Typology of mixes for world electricity production inventory for CLCA
A. Herbert, EDF R&D / Laboratoire de Génie Chimique U.M.R. 5503 CNRS/INP/UPS; C. Azzaro-Pantel, Laboratoire de Génie Chimique U.M.R. 5503 CNRS/INP/UPS; D. Le Boulch, EDF R&D
Over the past two decades, consequential LCA (CLCA) has emerged as a modelling approach to assess consequences of either direct or indirect changes. The development of CLCA has received a lot of interest from practitioners and requires specific inventory data. These data, often based on economic models are long to set and require a good understanding of processes. Moreover, no robust generalised technical databases for consequential LCI about indirect changes have been provided yet, especially in the case of electricity production, which may lead to uncertain LCIA results. In that context, the development of more generalized LCI data represents a major challenge for consequential LCA application. A first step to address this issue is to better understand electricity production mix worldwide. So, the aim of this work is to set a typology of electricity production mixes. The proposed typology is based on the analysis of two factors: the former involves the composition of electricity production mixes of 94 countries producing more than 10 TWh in 2012[1] and the latter is their calculated GHG (gCO_2eq/kWh) assessment from LCA using IPCC 2013 LCIA method[2]. The analysis of these two characteristics leads to the determination of a 4-group typology: very low (0-37), low (37-300), mean (300-600) and high (>600) emitting countries, each sharing general characteristics about electricity power generation, i.e., hydraulic/nuclear, hydraulic/nuclear and gas, gas, and coal/ fuel. The next step of our work is to study the dynamic evolution of some countries selected from each group of the proposed typology, using historical data. The first case study will be the France energy system. The comparison of historical and contemporary observed production data, as previously carried out in the literature[3] will help us to identify the uncertainty remaining in evaluating electricity production processes, and so the consequences of integrating such data in consequential LCI. \n[1]The Shift Project. 2012. TSP Data Portal. tsp-data-portal.org. Accessed 03/16/2015. [2]IPCC, 2013: Climate Change 2013: The Physical Science Basis. Cambridge University Press, Cambridge, United Kingdom and New York, 1535 pp [3]Mathiesen et al., « Uncertainties related to the identification of the marginal energy technology in consequential life cycle assessments », J. Clean. Prod., vol. 17, n°15, p. 1331-1338, oct. 2009

158
Multiple recycling loops in attributional LCA - Misconceptions and solutions
D. Schrijvers, University of Bordeaux; P. Loubet, G. Sonnemann, University of Bordeaux / The Life Cycle Group CyVi
Modelling of recycling in LCA has always been an important topic for discussion. It is often argued that the modelling method should reflect the benefits of multiple recycling loops. Some guidance on this area is given in ISO/TR 14049: the avoided burden method is proposed if the material is recycled without loss of inherent properties, and the number of (future) uses of the material is used to calculate the inventory per life cycle when the material undergoes changes in its inherent properties. However, it is questionable whether this guidance is suitable for attributional LCA. In the attributional database of ecoinvent 3, the life cycle inventory is partitioned over the co-products of multifunctional processes by "allocation at the point of substitution". We show that this method is equally applicable to materials that are recycled at the end of life. We propose a new formula that calculates the LCI of one life cycle of a material, considering the consumption and production of co-products and recycled materials in that life cycle. If the consumed recycled material has been recycled several times before, the formula can be solved to calculate the inventory after a definite or infinite number of recycling loops. The adapted formula can be applied when the material is recycled via a material pool where the inventory regarding the primary production, recycling activities and waste treatment are similar in other product systems, and the average recycled content and the end-of-life recycling rate in the material market can be determined. The LCI after a large number (>5) of recycling loops corresponds to the avoided burden approach as described by ISO/TR 14049, only when the recycled content and the end-of-life recycling rate are equal. This is not a realistic condition for most materials. Therefore, it is important to distinguish these rates, which is not done in the current application of the avoided burden method. Other methods that consider multiple recycling loops often refer to downstream recycling activities. We show that only multiple recycling loops in the past are relevant in an attributional LCA. Whether the produced recycled material at the end of life can be recycled again in the future, is outside the scope of an attributional LCA that focuses on one product life cycle.

159
Methodological Guidelines for the Life Cycle Inventory of Agricultural Products
X. Bengoa, Quantis; J. Lansche, Agroscope Reckenholz-Tänikon Research Station ART; V. Magaud, Quantis; P. Mouron, ART Agroscope; T. Nemecek, Agroscope / Institute for Sustainability Sciences ISS; E. Riedener, ART Agroscope; V. Rossi, M. Vargas, Quantis
In 2012, the sustainability consultancy Quantis[1] and Agroscope[2], the Swiss Federal research institution for agriculture, joined their forces to create a unique international consortium of nine major, global, private companies from the agro-food value-chain[3] and two governmental agencies[4] into what would become the World Food LCA Database (WFLDB) project. Three years later, 400 datasets for crops, animal products and food products in 40 countries were delivered to the project partners and submitted to the ecoinvent Centre for publication in 2016 and 2017. Thereby, the entirety of the project developments are made available to a broad public of LCA and sustainability practitioners. A major outcome of WFLDB was the development of the *Methodological Guidelines for the Life Cycle Inventory of Agricultural Products**[5]***, a detailed and comprehensive guidance for inventory modelling of agricultural and food systems. To date, these are among the very few – if not the only – peer reviewed documents providing detailed and operational guidance applying to a wide variety of agricultural systems and countries, from farm to plate. The *Guidelines* are based on existing scientific emission models and are compliant with the most recognised standards (ISO, ILCD, ecoinvent, IPCC). They are also to a large extent aligned with draft Product Environmental Footprint Category Rules (PEFCR) for several sectors. All key methodological issues relevant to agro-food systems are addressed, such as the definition of system boundaries, co-products allocation, inventory modelling for fertiliser and pesticides, emission flows, water modelling and land use change. A unique set of data collection principles combining statistical data from FAO and agronomic extrapolations was applied to generate consistent LCI data. Innovative approaches were developed where no global consensus is yet available, such as the modelling of land use change. The *Guidelines* were first made public in August 2014 and then updated in July 2015. The current version (v3.0) aims to serve as an open reference for LCA practitioners and LCI database developers. The second phase of the WFLDB project, starting in 2016, will further work on improving datasets and expanding these guidelines in cooperation with all stakeholders. Thereby we consider the latest methodological developments and global consensus on key topics such as pesticides emissions modelling, land use change or carbon sequestration in

grassland.

160
Process simulation to improve LCI modelling of new technologies - Case study on source-separated urine treatment
E. Igos, Luxembourg Institute of Science and Technology (LIST) / Environmental Research and Innovation; M. Besson, Luxembourg Institute of Science and Technology; E. Benetto, Luxembourg Institute of Science and Technology (LIST) / Environmental Research and Innovation; A.B. Bisinella De Faria, L. Tiruta-Barna, M. Sperandio, A. Ahmadi, Université de Toulouse / INSA UPS INP LISBP
Data collection for Life Cycle Assessment (LCA) of new technologies appears to be challenging (instability of lab/pilot scale, up-scaling uncertainties). The integration of these computational tools within Life Cycle Inventory (LCI) models could be beneficial to the stability and consistency of LCA. This line of research has been followed within the FP7 project ValuefromUrine, where an innovative urine treatment (VFU) has been developed to recover nutrients and increase Waste Water Treatment Plant (WWTP) efficiency. Three scenarios are tested: (i) *Reference* (conventional WWTP), (ii) *small VFU* (pilot scale VFU installed in buildings treat 10% of urine) and (iii) *large VFU* (up-scaled VFU integrated in WWTP treat 50% of urine). The functional unit is the treatment of 1 m^3 of wastewater. Foreground processes are simulated through Python functions for VFU technology (mass balances, electrochemistry, engineering) and SUMO process engineering tool for WWTP. These models, currently under validation, depend on input variables (design parameters, scenario variables, assumptions) for which uncertainty can be defined. The LCI outputs are integrated in the open-source Brighway2 tool. The fertilizers and energy recovered are assumed to avoid the production of conventional market products. Preliminary results, focusing on VFU technology, shows the influence of molar ratio dosing Mg:P on LCI data (other design parameters will be later analysed). Increasing this ratio generates additional impacts linked to magnesium chloride consumption but is also beneficial regarding the avoided production of phosphate-based fertilizer. The environmental profile of VFU technology is mainly driven by the consumption and transport of chemicals, polypropylene (in infrastructures) and the avoided production of fertilizers. The main innovation in this work is the integration of process simulation tools with LCI modelling, in order to cope with the lack of data for new technologies (e.g. use of complex and reliable modelling tools) and to improve results interpretation (data relationships, uncertainty analysis, etc.). Furthermore, this approach, coupled to an optimization algorithm, could determine the optimal design parameters. The authors also stress the difficulty to perform advanced modelling and analyses with commercial LCA software. The use of an open-source platform such as Brightway2 solves the problem but requires programming competences (potential barrier for LCA practitionners).

161
Impacts of severe wet-weather events: How to account for temporal variability of unmanaged peak flows in an urban sewage treatment system?
E. Risch, IRSTEA Montpellier / UMR ITAP; j. gasperi, LEESU / LEESU laboratoire eaux environnement et systèmes urbains; M. Gromaire, ParisEst University / LEESU laboratoire eaux environnement et systèmes urbains; G. Chebbo, ParisEst University / Leesu; S. Azimi, SIAAP / Direction du Développement et de la Prospective; V. Rocher, SIAAP; P. Roux, National Research Institute of Science and Technology for Environment and Agriculture Irstea / UMR ITAP ELSA; R.K. Rosenbaum, National Research Institute of Science and Technology for Environment and Agriculture - Irstea / UMR ITAP; C. Sinfort, Montpellier SupAgro / ELSA Group UMR ITAP
In typical life cycle impact assessment (LCIA) studies of urban wastewater systems (UWS), average conditions are modelled but there are many annual flooding events with releases of untreated sewage. Such peak conditions are not considered and present a high temporal variability which is not currently accounted for. In addition, the aggregation of the loads from several storm events could bring an issue for the impact assessment on the aquatic categories of eutrophication and ecotoxicity. Hence we are investigating the contributions of these wet weather-induced discharges along with the inclusion of temporal variability in the life cycle inventory (LCI) for UWS. In the framework of the OPUR research programme (Observatory of Urban Pollutants) and in collaboration with the Paris public sanitation service (SIAAP), this work aimed at identifying and describing contributing flows from the UWS in the Paris area by a selection of routine wastewater parameters and priority pollutants. This collected data is organized according to archetypical weather days over a 24-hr span. Secondly, for each archetypical weather days and its associated flows to the receiving river water (Seine) the parameters of pollutant loads (statistical distribution of concentrations and volumes) are determined with statistical treatment of data. Then, the inventory flows (i.e. the potential loads from the UWS) can be used as inputs in a classical LCA to investigate the relative importance of episodic wet weather versus “continuous” dry weather loads coupled to further uncertainty analysis using a Monte Carlo method. Results analysis showed that a few severe events can be important contributors to the total annual pollutant load on some parameters (routine wastewater pollutants but also priority pollutants). The proposed method based on the definition and characterization of archetypical weather days has shown the appropriate level of temporal differentiation in the LCI to assess the impacts from unmanaged pollutant loads from UWS during intense storm events. With such significant contributions of pollutant loads at the LCIA level, further research is required to include temporally-differentiated emissions in the methodological framework of the aquatic categories of eutrophication and ecotoxicity, to better understand how the performance of an UWS system affects the receiving environment for given local weather conditions.

Innovative techniques for monitoring chemicals in the environment

162
Analysis of 42 pesticides in fresh fish muscle by dispersive solid phase extraction with QuEChERS followed by LC-MS/MS analysis
M. Lopez de Alda; N. Guillem-Argiles, J.I. Simionato, CSIC   Spanish National Research Council / Institute of Environmental Assessment and Water Research IDAEA; D. Barcelo, IIQAB-CSIC / Dept Environmental Chemistry
Multi-residue analytical methods for determination of pesticides in biota samples are scant in the literature. The present study describes a high sensitivity and selectivity method based on dispersive solid phase extraction with QuEChERS followed by liquid chromatography-tandem mass spectrometry (LC-MS/MS) analysis for determination of a range of different polarity pesticides in fresh fish muscle and its subsequent application to various real samples in order to, first, prove its suitability, and, secondly, have a first picture of the occurrence of the compounds investigated in the matrix under study. A total of 49 pesticides, belonging to the classes of organophosphorus, pyrethroids, carbamates, triazines, ureas and chloroacetamides, among others, were initially considered for analysis. Extraction of the pesticides from the biota samples (10 g) was performed with QuEChERS kits using acetonitrile (1:1 w/v), 4g $MgSO_4$, 1g NaCl, 1g NaCitrate and 0.5 g disodium citrate sesquihydrate, and subsequent clean-up with 400 mg PSA, 400 mg C18 and 1200 mg $MgSO_4$. LC was performed with a Purospher STAR RP-18e column (125 × 2 mm, 5 μm). MS/MS detection was carried out in the selected reaction monitoring (SRM) mode with a triple-quadrupole mass spectrometer equipped with an electrospray (ESI) interface working in both positive and negative ion modes along the analytical run. Quantification was performed by the isotope dilution method, based on the peak areas obtained for the analytes and their deuterated analogues. The performance of the analytical method was evaluated in terms of linearity, sensitivity, accuracy, matrix effects and precision, according to the guidelines set for pesticide residues analysis in food and feed (SANCO/12495/2011), with satisfactory results for 42 out of the 49 initially considered compounds. As regards sensitivity, most of the target compounds could be determined at levels below 10 ng/g. Application of the method to a set of real samples showed the presence of some of the target compounds in fish muscles at relatively low levels (in the ng/g range). Main advantages of the method are, in addition to high sensitivity and selectivity, simplicity, rapidity and relatively low cost. *Acknowledgement* - The authors thank the financial support of the EU (FP7 projects GLOBAQUA (265264) and SOLUTIONS (603437)) and the Generalitat de Catalunya (Consolidated Research Groups “2014 SGR 418 - Water and Soil Quality Unit” and 2014 SGR 291 - ICRA).

163
Development of new analytical techniques for monitoring of POPs and emerging environmental contaminants
Y. Sapozhnikova, USDA / ARS; L. Han, China Agricultural University / College of Science; J. Matarrita-Rodríguez, Universidad de Costa Rica UCR / Centro de Investigación en Contaminación Ambiental; S. Lehotay, USDA / ARS
Reliable and accurate analytical techniques are essential in order to study the occurrence, behavior, and fate of known and emerging environmental contaminants. The aim of this work was to develop a fast, simple, high-throughput analytical method for simultaneous determination of diverse persistent organic pollutants (POPs): carcinogenic PAHs, dioxin-like PCBs, and PBDEs and other flame retardants (FRs) along with diverse pesticides in a single analysis to improve the monitoring of these contaminants. Sample preparation for biological samples including fish (catfish, salmon, wreckfish) and shrimp was based on quick, easy, cheap, effective, rugged and safe (QuEChERS) extraction with acetonitrile followed by clean-up using dispersive solid phase extraction (d-SPE). The sample preparation is fast and inexpensive, where one analyst can prepare a batch of 10 pre-homogenized samples in one hour, using approximately $3 of materials per sample. The analysis entails fast low-pressure (LP) gas chromatography (GC) tandem triple quadrupole mass spectrometry (MS/MS) allowing separation of over 200 compounds and internal standards in 10 min. Satisfactory recoveries (70-120%) were achieved for the majority of analytes with relative standard deviations under 20% even at 1-5 ng/g spiking levels. To minimize sample size, and reduce amounts of organic solvents and internal standards added before the extraction, we evaluated variables affecting QuEChERS-based extraction yields of incurred contaminants in fish samples. Our results demonstrated that 2 g subsamples were adequate for analysis of the

incurred contaminants. Smaller test portion size often translates into faster, easier, and less wasteful methods, provided that the subsample adequately represents the original sample. To further improve identification of contaminants and to achieve lower detection limits, we are currently evaluating a new Agilent 7010 high sensitivity MS/MS. Also, novel lipid-removal materials and new sorbents were recently evaluated for the analysis of contaminants in salmon. The monitoring data on the occurrence of these contaminants may advance our understanding of their potential risk and aid in future risk assessment for the better protection of human health and the environment.

Two-dimensional algal arrays as innovative biosensing tool

C. SUSCILLON SIEBMAN, University of Geneva / Section of Earth and Environmental Sciences Institute Forel; O.D. Velev, North Carolina State University / Department of Chemical and Biomolecular Engineering; V. Slaveykova, University of Geneva / Section of Earth and Environmental Sciences Institute Forel

Because of their rapidity and sensitivity, microalgal biosensors can be used as early warning systems to detect early effects on organisms exposed to chemical in environmental samples. Among all the biological endpoints explored in whole-cell biosensors, chlorophyll *a* fluorescence is known as a routine technique for the determination of the stress effect and reactive oxygen species (ROS) production is becoming a promising key marker to evaluate chemicals toxicity in the environment. However reproducible immobilization of the living cells in facile array format for biosensing is still challenging and their viability is difficult to maintain. In this context, alternative current (AC) dielectrophoresis (DEP) allows a rapid and reversible assembly of live cells from aqueous sample. In our study, an alternative current (AC) dielectrophoretic lab-on-chip setup was evaluated as a rapid tool to collect and assemble cells of microalga *Chlamydomonas reinhardtii* in two-dimensional (2D) arrays. Combined with fluorescence microscopy detection, the capability of using the 2D whole cell arrays to follow the algal sub-toxic response to several environmental contaminants, including mercury, methylmercury, copper, copper oxide nanoparticles (CuO-NPs), and diuron was explored. The results showed significant increase of the cellular ROS when *C. reinhardtii* was exposed to increasing concentrations of methylmercury, CuO-NPs and 10^{-5} M Cu, as revealed by enhancement of the CellROX® stain cells. Less sensitive to short term exposure to contaminants was algal autofluorescence, which decrease only upon exposure Hg, CuO-NPs and high concentrations of copper. Overall, this study demonstrates the potential of combining of AC-dielectrophoretically assembled two-dimensional algal array with fluorescence detection, alone or in combination with fluorescence stain, as a rapid and multiplex biosensing tool for environmental chemicals and toxins. Indeed, this tool allowed simultaneous monitoring of the temporal trends in cellular ROS generation and chlorophyll *a* fluorescence and significant results were detected in less than 2h.

Buleté, Institut des Sciences Analytiques / UMR Equipe Traces rue de la Doua Villeurbanne France; J. Garric, Irstea Lyon / Ecotoxicological Laboratory; E. Vulliet, CNRS / TRACES Team

Over the last decades, human activities (industries, agriculture, transports, consumption, urbanization…) and their impacts on the environment have not ceased to increase. Many molecules related to these activities are released to the environment and their occurrences within aquatic ecosystem become an important issue. In particular, the dose-response relationships of emerging pollutants on organisms at lower trophic levels remain little-known. In order to conduct biomonitoring studies, it is necessary to acquire knowledge about the kinetics of bioconcentration and depuration of these molecules within species, taking into account the inter-individual variability. In this context, an innovative analytical method was developed to quantify, in an amphipod crustacean (*Gammarus fossarum*), three emerging micropollutants known as anthropic pollution markers: carbamazepine, oxazepam and testosterone which are respectively an anticonvulsant, an anxiolytic and an endogenous hormone. A salting out liquid-liquid extraction, known as QuEChERS (Quick, Easy, Cheap, Effective, Rugged and Safe) was miniaturized and optimized. The miniaturization of the method made it possible to adapt to the low mass sample (approximatively 5 mg dry weight) and to perform the analysis at the scale of a single organism. Beside an efficient sample preparation, ultra-trace analysis of compounds in such matrices of small size requires a good sensitivity. Therefore, an original coupling was developed. It consisted of a separation by nanoliquid chromatography (nanoLC) coupled to tandem mass spectrometry using multiple reaction monitoring cubed mode (MRM^3). For the nanoLC separation, a preconcentration system by on-column trapping was optimized to increase the injection volume. In order to keep both sensitivity and selectivity, detection is usually performed by mass spectrometry in multiple reaction monitoring mode (MRM). Nevertheless, proteomic studies showed that sensitivity and selectivity could be improved using MRM^3 mode. This technic was developed in this project and compared to the classic MRM. In the best of our knowledge, this was the first time that $MRM^3$was used for small molecule (The analytical strategy developed allowed to obtain limits of quantification lower than 1 ng.g^{-1} (wet weight) and to establish the kinetics of bioconcentration of contaminants within *G. fossarum*.

Time Integrating, Micro Flow, In-line Extraction (TIMFIE) sampler for determination of pesticide concentrations in water - a new quantitative tool in pollution monitoring

O. Jonsson, E. Paulsson, Swedish University of Agricultural Sciences (SLU) / Department of Aquatic Sciences and Assessment

There is a gap between the need for adequate concentration measurement of pesticides and other organic pollutants in water and the usefulness of the field sampling procedures available. In response to this a new device for quantitative, time integrated whole water sampling and simultaneous in-field extraction has been developed. The TIMFIE sampler is easily assembled from inexpensive laboratory consumables and requires no electricity or other supporting equipment. It consists of a simple syringe pump connected to a flow restrictor (PEEK capillary) that enables a low microliter per minute water flow through an in-line solid phase extraction (SPE) cartridge. The force that slowly fills the syringe is accomplished by attaching a rubber band or a weight to the piston, or through applying under pressure in the syringe by pulling and locking the piston prior to sampling. Target compounds are continuously extracted and trapped on the SPE material during the sampling period. The extracted water ends up in the syringe barrel and after finished sampling the sample volume is determined and the SPE cartridge sent to the analytical lab where it is handled according to standard protocols, typically followed by gas or liquid chromatography coupled to mass spectrometric detection. Method development and validation is similar to standard SPE procedures and the large number of SPE packing materials available together with the possibility of stacking cartridges in series offers flexibility. The flowrate, and in the end the sample volume, will mostly depend on the force applied, the diameter of the syringe and the diameter and length of the restrictor, but also on e.g. temperature since this affects water viscosity. By altering the controllable variables of the TIMFIE sampler the flow can be adjusted to enable sampling periods from hours up to weeks. The final volume collected during a certain time period will differ between sampling occasions, but the sampled/extracted water volume will always be determined with good accuracy, thus enabling quantitative analysis. The TIMFIE sampler offers:\n - Time-averaged sampling of whole water. \n - Quantitative determination of compound concentrations by well-defined procedures. \n - Low price, easy assembling and high flexibility. \n - Minimised costs for shipping and storage of samples. Experiences and results from lab and field experiments looking at pesticides in surface water will be presented.

High throughput microbial array for complex matrix assessment

M. DURAND, University of Nantes / IUT Genie Biologique; A. Hua, University of Nantes / CNRS UMR GEPEA; S. Jouanneau, University of Nantes / GEPEA CNRS UMR CBAC Laboratory; M. Cregut, University of Nantes / GB; T. Gerald, University of Nantes / Microbiology

Ecotoxicological assessment using different bioassays for environmental sample are largely used this last 20 years. Amoung them recombinant bioluminescent or fluorescent bacterial bioassays have been developed to determine the presence and the toxic effect of pollutants, because even if chemical analysis are sensitive and specific, they failed in the determination of the bioaccessibility and biodisponibility of the pollutant. All the recombinant bacteria carried out fusion between reporters genes (*lux* CDABE for bioluminescence and gfp for fluorescence) and the promoter of genes involved in metal resistance mechanisms (for metal detection) or genes involved in degradation of organic compounds. These bioassays are generally not specific for one compound, in particular those dedicated for Metal trace element (MTE), leading to a difficult application in complex media. In order to overcome this problem, we used an array of bioluminescent and fluorescent recombinant bacteria with different cross-sensitivity to MTE and organic pollutant. We combined the bacterial response of all the bacteria to obtained a database. In a frist approche we used a set of bioluminescent recombinant bacteria sensitive to MTE, we build a database with the results of the induction of the bacteria exposed to 15 metal and metal mixture. Four specific decision trees based on CHAID algorithm were designed and tested on waste water. The result showed that the concentrations of MTE detected by our model match the chemical measurements. In a second approche we completed our panel of bioluminescent bacteria to improve our model by using a collection of 1930 fluorescent bacteria. Prelimimary results obtained on complexe envrionmental samples (wood-waste leachates) showed variation of bacterial response according to the contamination allowing an interesting method of screening. We propose a mixture of targeted and non targeted highthroughput arrays of bacteria to describe more realistically the toxicity of very unusual complex matrix combined with data mining interpretation.

Biological effects of emerging micro pollutants at realistic

environmental concentrations (I)

Non-steroidal anti-inflammatory drug diclofenac disturbs the prostaglandin system in the marine mussel Mytilus galloprovincialis

F. Courant, Université de Montpellier - UMR 5569 Hydrosciences; L. Arpin-Pont, Université de Montpellier - UMR 5569 Hydrosciences / UMR Hydrosciences Montpellier; B. Bonnefille, S. Vacher, M. Picot-Groz, Université de Montpellier - UMR 5569 Hydrosciences; E. Grousset, Université de Montpellier - UMR 9190 MARBEC; E. Gomez, Université de Montpellier, Hydrosciences Montpellier UMR 5569 / Sc Environnement Sante Publique; H. FENET, Université de Montpellier - UMR 5569 Hydrosciences / UFR des Sciences Pharmaceutiques

Human pharmaceuticals, such as nonsteroidal anti-inflammatory drugs (NSAIDs), are an emerging environmental threat to marine organisms. Bioaccumulation in aquatic organisms along with possible ecotoxicological effects may then be of concern, as shown by the inclusion of diclofenac (DCF) in the first watch list by the EU Water Framework Directive. It is possible to hypothesize that these compounds will be pharmacologically active in organisms in which the drug targets are expressed and functional. In humans, NSAIDs act through inhibition of cyclooxygenase (COX) conversion of arachidonic acid into prostaglandins. PGs are conserved lipid signaling molecules that mediate a wide array of biological functions [1]. There have been many reports of PG biosynthesis in a broad range of invertebrates, including bivalves [2]. Therefore, modulation of PG production in marine bivalves following exposure to DCF is worth questioning. The objective of this study was thus to investigate whether diclofenac (DCF) affects PG levels in marine mussels *Mytilus galloprovincialis*. An experiment was carried out whereby marine mussels were exposed to DCF for 48 h to 1 and 100 μg/L DCF. A specific and sensitive analytical method using liquid chromatography tandem mass spectrometry was developed to quantify DCF accumulation in marine mussel tissues. The developed method could also clearly identify and quantify prostaglandins PGE_2, PGD_2 and $PGF_2\alpha$ levels in mussel tissue and be used to assess their modulation following DCF exposure. Measured concentrations of DCF in water were relatively close to the nominal concentrations for all exposed aquaria. A low bioconcentration was calculated at 26.4 L/kg. The weak bioaccumulation of DCF observed is consistent with its possible biotransformation in the organisms, supported by the detection of hydroxy-diclofenac metabolites in exposed organisms and water. Basal PGE_2 concentrations ranged from under the limit of detection (LoD) to 202 μg/kg dw. PGD_2 was always found below the LoD. A downward trend in the PGE_2 concentration was observed between non-exposed mussels and those exposed to 1 μg/L DCF, whereas this decrease was confirmed and statistically significant for exposure to 100 μg/L. PGF2a globally ranged from 90 to 518 μg/kg dw. No difference was observed for $PGF_2\alpha$ levels between controls and exposed organisms. [1] Tootle, T.L., 2013. Int. J. Biochem. Cell Biol. 45, 1629–1632. [2] Martinez, G. et al. 1999. J. Exp. Zool. 284, 225–231.

Effects of Gadolinium-based contrast agents used in magnetic resonance imaging on freshwater mussels.

E. Perrat, Laboratory LIEC CNRS UMR UdL; M. Parant, Universite de Lorraine; C. Rosin, ANSES; C. Cossu-Leguille, Universite de Lorraine

Contrast agents based gadolinium (Gd-CA) are often used in Magnetic Resonance Imaging (MRI). After blood injection these compounds are released by urinary rejection. Due to the lack of specific recycling process in European Waste Water Treatment Plants (WWTPs), these pharmaceutical compounds enter the aquatic environment from river to tap water (Bau & Dulski, 1996). Until now, the effects of these compounds on living organisms has been approached in medical conditions i.e. 10^5 μg.L^{-1} range of concentration. During this study, toxicity and bioaccumulation of Gd-CA were followed at realistic environmental concentrations on two species of freshwater mussels (*Corbicula fluminea* and *Dreisseina bugdensis*). Gd concentrations and bioconcentration factors (BCF) were measured in mussels' tissues by ICP-MS analysis in bivalves exposed during 7 and 21 days : (i) *in situ* along a section of the Mosel River located around WWTP output and (ii) in laboratory in presence of the most currently used Gd-CA (Dotarem®) in realistic concentrations (1 and 10 μg.L-1) according to our previous studies (Perrat *et al.,submitted*). Moreover, ecotoxicological effects were evaluated via a battery of complementary biomarkers in mussels, i.e. catalase (CAT), caspase-3 (CSP-3), glutathione-S-transferase (GST), acid phosphatase (ACP), glutathione peroxidase (GPx), lactate dehydrogenase (LDH), lipid peroxidation (LOOH), electron transport system attached to the mitochondria (ETS), and the total antioxidant capacity (TAC). Our results showed an increase of Gd concentrations in the digestive gland of mussels after 21 days of exposure; however Gd-CA is less accumulated by *Corbicula fluminea* (BCF = 11) than *Dreisseina bugdensis* (BCF = 20). In laboratory, no mortality was observed on bivalves. Biomarkers measurements showed an impact of Gd-CA on bivalves suggesting establishment of detoxification mechanisms in *Corbicula fluminea* tissues; e.g. an increasing of TAC level for *Dreisseina bugdensis* after 7 days of exposure. Gd-CA exposition seems to induce antioxidant mechanisms to protect the organism (Doherty *et al*., 1987). This study presents ecotoxicological effects and accumulation of Gd in bivalves in realistic conditions of exposure to Gd-CA. To go further, we will implement bioaccumulation and toxicity assays with other aquatic organisms and effects along a short trophic chain (algae-daphnids-fish).

The marine mussel Mytilus galloprovincialis bioconcentrate and metabolize antidepressant pharmaceutical venlafaxine

E. Gomez, Université de Montpellier, Hydrosciences Montpellier UMR 5569 / Sc Environnement Sante Publique; C. Boillot, Université Montpellier 1; M. MARTINEZ BUENO, Université de Montpellier - UMR 5569 Hydrosciences / Hydrosciences Montpellier; D. Munaron, IFREMER / Laboratoire Environnement et Ressources du LanguedocRoussillon; O. Mathieu, CHU Montpellier / Département de Pharmacologie Médicale et Toxicologie Hôpital Lapeyronie; H. FENET, Université de Montpellier - UMR 5569 Hydrosciences / UFR des Sciences Pharmaceutiques

A significant investment in research has been conducted to define exposures and potential hazards of pharmaceuticals in freshwater and terrestrial ecosystems. In contrast, comparatively few empirical studies have been conducted for pharmaceuticals that are likely to enter coastal and marine ecosystems[1,2]. The antidepressant venlafaxine (VLF) and some of its metabolites were recently found in mussels caged in a coastal site receiving treated wastewater[3]. In those marine organisms, very scarce data is available on the accumulation and/or metabolisation of pharmaceuticals. Consequently, it appears hazardous to conclude on the origin of those metabolites in mussels, which could include a bioaccumulation through direct exposure as well as a metabolism of VLF in mussels. The aim of the present work was to quantify the accumulation of VLF in the marine mussel Mytilus galloprovincialis and to evaluate the possible metabolism in laboratory controlled experiments. The accumulation of VLF was evaluated in the whole mussel tissues after 1, 3 and 7 days of semi-static exposure by water (10μg L-1day-1) followed by 1, 3 and 7 days of depuration. Under those conditions, VLF attained an average tissue concentration of (n=3) 2146.3 ± 156.0 ng g-1 dry weight (d.w.) in seven days. The kinetic bioconcentration factor (BCF) was 265 ± 19 L kg-1 d.w. Seven days of depuration allowed a decrease of tissue concentration to 21 ± 1.0 ng g-1 d.w. Four VLF metabolites were quantified in mussel tissues and excreted in water. The kinetics of those metabolites in water confirmed the metabolism of VLF by mussels. Complementary experiment conducted at 1, 10 and 100 μL L-1 nominal concentration clearly confirmed that M. galloprovincialis metabolize VLF, with the quantification of studied metabolites excepted the NNO-VLF. These results gave a first approach on the ability of mussel to metabolize pharmaceuticals. Together with bioaccumulation information, this study provided a first approach on the pharmacokinetics of a pharmaceutical in a wild marine species, underlining the need of further experiments to better understand how venlafaxine modulate the receptors in mussels and how exposure to this antidepressant affects physiological functions of invertebrates. Mechanism study for cardio negative effect of propranolol to Daphnia magna by utilizing acute toxicity syndrome

T. Jeong, Gwangju Institute of Science and Technology

Acute toxicity syndrome is a set of biological responses in behavioral, physiological parameters resulted from distinguishable toxic mechanism. In aquatic toxicology field, monitoring study for the syndromes has been conducted to fish and has proven ability to categorize chemical agents based on their mechanism of action because different molecular stimulation result in different visible outcomes. In this study, we tried to distinguish mode of action of propranolol, a human pharmaceutical ingredient, which is usually considered as a baseline toxic chemical to aquatic non-targeted species based on lethal concentration from QSAR. *Daphnia magna* was employed as a model organism and not only phenotypical outcomes but also metabolomics profiling were monitored for more stereoscopic insight in mechanism characterization. Narcotic agents (4-chloroanilin, ethylacetate), β-adrenergic receptor and 5-hydroxytryptamine receptor antagonists (nadolol, yohimbine, cyproheptadine) were treated with propranolol to *Daphnia magna* and their syndromes were compared to categorize potential mechanism of propranolol. Syndromes include swimming behavior, heartbeat and metabolite profiling. In the time series monitoring during 24h of swimming behavior, *Daphnia magna* tend to be deactivated at high concentration of propranolol. Likewise, nadolol and yohimbine showed hypo activity as time goes by in effective concentrations. In opposite, exposure of cyproheptadine resulted in hyper activity and narcotic agents showed recovery in swimming activity after severe temporary deactivation. Activity-concentration relationship was compared between swimming behavior and heartbeat at 6h. Although propranolol exposure affect to both swimming behavior and heartbeat, heartbeat was decreased at concentrations where no effect on swimming behavior was observed. Most similar pattern was observed from nadolol exposure and yohimbine also showed similar relationship with higher effect on swimming activity. For 4-chloroaniline and ethylacetate, swimming behavior was so sensitive that several concentrations showed deactivation without significant heartbeat effect. NMR Analysis is now being conducted for metabolite profiling and the result will be combined and be presented. We expect that metabolite profiling provide information how metabolism balance changed with chemical exposure and stricter categorization tool by integration with visible outcomes described above.

Environmentally relevant concentrations of antidepressants alter behaviour and gene expression in amphipods

A. Ford, A. Green Extabe, University of Portsmouth / Biological Sciences; M.C. Bossus, University of Portsmouth; S. Short, S. Kolher, University of Portsmouth / Biological Sciences; A. Love, Sparsholt College / School of Biological Sciences; Y.Z. Guler, University of Portsmouth

The effects of antidepressants on wildlife are currently raising some concern due to an increased number of publications indicating biological effects at environmentally relevant concentrations (< 100ng/L). These results have been met with some scepticism due to the higher concentrations required to detect effects in some species and the perceived slowness to therapeutic effects recorded in humans and other vertebrates. Since their mode of action is thought to be by modulation of the neurotransmitters serotonin, dopamine, and norepinephrine, aquatic invertebrates that possess transporters and receptors sensitive to activation by these pharmaceuticals are potentially affected by them. We highlight studies on the effects of antidepressants, on particularly crustacean groups showing they are susceptible to a wide variety of neuroendocrine disruption at environmentally relevant concentrations (< 100ng/L). Behavioural and transcriptional changes in this crustacean were studied when exposed to the most prescribed SSRIs (citalopram, sertraline and fluoxetine), SARI (trazodone) and SNRI (duloxetine). The animals were exposed to these five drugs at environmentally relevant concentrations from 0.001 to 1 μg/L during short-term (1 hour and 1 day) and medium-term (8 days) experiments. The movement of the amphipods was tracked using the behavioural analysis software during 12 min alternating dark/light conditions. Antidepressant concentration had a significant effect ($p < 0.01$) on velocity for Duloxetine (1hr, 1day & 8days); Sertraline (1hr & 1day) and Fluoxetine (1day) but not trazodone or citalopram ($p > 0.05$). We have also applied high-throughput sequencing technology to animals exposed to 100ng/L concentrations of sertraline, fluoxetine and duloxetine to reveal the broad transcriptomic responses to these compounds. Preliminary analysis of gene expression profiles indicates a broad range of potential neurological pathways confirming that these drugs have multiple targets. In the light of new studies indicating effects on the human brain with just of dose of SSRIs using MRI scans, we discuss possible reasons for the discrepancy in former results in relation to the "read-across" hypothesis.

Ecotoxicology and risk assessment of nanomaterials - Interactions at nano-bio interface (II)

Eco-interactions of engineered nanoparticles in sea water media and implications for toxicity

G. Grassi, University of Siena / Department of Physical Earth and Environmental Sciences; e. bergami, University of Siena / Physical Earth and Environmental Sciences; E. Bocci, University of Siena; L. Manfra, Institute for Environmental Protection and Research; M.P. Monopoli, University College Dublin / Centre for BioNano Interactions School of Chemistry and Chemical Biology; A. Salvati, University of Groningen / Groningen Research Institute of Pharmacy Division Pharmacokinetics Toxicology and Targeting; A. Atrei, University of Siena / Department of Biotechnology Chemistry and Pharmacy; K.A. Dawson, University College Dublin / Centre for BioNano Interaction School of Chemistry and Chemical Biology; I. Corsi, University of Siena / Department of Physical Earth and Environmental Sciences

The physico-chemical properties of engineered nanoparticles (NPs) such as specific surface charges might play a crucial role in their behavior in complex natural media as sea water, with implications on cellular uptake and toxicity in exposed organisms. In this study, we investigate the ecotoxicity of nano-TiO_2 (25 nm), PS-COOH (40 nm) and nano-SiO_2 (100 nm) as model of negatively charged NPs with different size and inner core in order to evaluate their suitability for NPs screening based on their interactions with natural sea water media (NSW). Marine green microalgae *Dunaliella tertiolecta* and brine shrimp *Artemia franciscana* were used as model species in standardized acute (72h and 48h) and long-term (7d) ecotoxicity tests. A detailed physico-chemical characterization of all three NPs in NSW and in comparison to artificial sea water (ASW) and Milli-Q water (Milli-Q) was performed. Given their common negative surface charge, the effect of abundant background bivalent and monovalent counter ions in NSW on the suppression of electric double layer was dramatic and lead to strong aggregation. HR-TEM of nano-TiO_2 suspended in NSW revealed a complex matrix around aggregates, forming corona-like structures (eco-corona), further confirmed by DCS analysis. Ecotoxicity tests showed a common pattern of no toxicity for all three NPs in the range of the tested concentrations (0.1-100 mg L^{-1}) for both microalgae and brine shrimps. Nano-TiO_2 and PS-COOH resulted massively sequestered inside the gut lumen of brine shrimp larvae while nano-SiO_2 aggregates were barely detectable probably due to their optical transparency. Our findings suggest that negative surface charges drive substantial aggregation of NPs in NSW thus limiting uptake and consequently toxicity in exposed organisms. Therefore ecotoxicity coupled with a detailed physico-chemical characterization in the suspension media might be used as suitable tool to predict behavior and potential adverse effects of NPs in the marine environment.

174

Are trophic interactions between aquatic invertebrates affected by AgNPs exposure route?

D. Batista, University of Minho / Centre of Molecular and Environmental Biology CBMA; D. Giling, Institute of Freshwater Ecology and Inland Fisheries (IGB) / Department of Experimental Limnology; C. Pascoal, F. Cássio, University of Minho / Centre of Molecular and Environmental Biology CBMA Department of Biology; M.O. Gessner, Leibniz Institute of Freshwater Ecology and Inland Fisheries IGB

Silver nanoparticles (AgNPs) have been increasingly used over the last decade, resulting in their growing release into freshwater ecosystems, where AgNPs and ionic Ag derived from NPs can have toxic effects on aquatic species and compromise important processes such as organic matter use and decomposition. However, little is known about how species interactions in multi-trophic systems will affect such ecosystem processes when exposure routes of AgNPs vary. The goal of this study was to assess the impacts of low doses of AgNPs and Ag^+ on trophic interactions between aquatic invertebrates and consequent ecosystem effects. Specifically, we assessed the importance of both direct (via water) and indirect (via food) exposure routes by exposing a simplified detrital food web, comprising leaf litter, microbes, a shredder species and collector species to: (i) water contaminated with AgNPs (0, 1, 100 $\mu g\ L^{-1}$) or $AgNO_3$ (0, 0.1 $\mu g\ L^{-1}$), and (ii) leaves contaminated for 6 days with AgNPs and $AgNO_3$ at the same concentrations. Shredders (*Gammarus pulex*, Gammaridae, Amphipoda) and collectors (*Habrophlebiodes sp*., Leptophlebiidae, Ephemeroptera) were placed in laboratory feeding containers where collectors had access to fine particulate organic matter (FPOM) produced by *G. pulex*, but were separated by a mesh screen. Leaf consumption and FPOM production by *G. pulex* as well as fungal biomass and decomposition activity were determined after 15 days. The stress induced by AgNPs and Ag^+ in both invertebrate species was assessed by measuring the activity of antioxidant and neuronal enzymes. Microbial decomposition was lower by direct exposure to AgNPs and Ag^+, whereas leaf consumption by *G. pulex* only decreased when leaves were contaminated with the lowest concentration of AgNPs. There were no effects on FPOM production. Changes in the activity of a key antioxidant enzyme, catalase, indicated stress caused by AgNPs and Ag^+ in both invertebrate species, mainly in response to direct exposure. Overall our results demonstrate that ecological effects on different functional groups of stream invertebrates vary with exposure route of AgNP at environmentally realistic concentrations. Thus the pathway by which stream food webs are exposed to AgNPs will influence the impacts of AgNPs on food-web components and the processes in which they are involved.

175

Food chain transfer of silver nanowires in aquatic ecosystems

Y. Chae, Konkuk University; Y. An, Konkuk University / Department of Environmental Heath Science

Nanowires, which are increasingly being used in various industries, may have different adverse ecological effects from those of zero-dimensional nanoparticles, which have been widely studied. We investigated the direct and indirect (trophic) effects of two sizes (10- and 20-μm long) of silver nanowires (AgNWs) on a three-species aquatic food chain consisting of algae (*Chlamydomonas reinhardtii*), water fleas (*Daphnia magna*) that feed on algae, and their predators zebrafish (*Danio rerio*). We assessed the direct toxicity of AgNWs for algae and water fleas, and documented the transfer of AgNWs absorbed by algae to water fleas fed with exposed algae, and eventually to zebrafish fed with exposed water fleas. We found that AgNWs directly inhibit growth in algae, and destroy the digestive organs of water fleas. We also found that AgNWs can be transferred through food chains, and can enter and impact the bodies of organisms in higher trophic levels, such as the fish in this study, implying that nanomaterials have the potential to eventually enter human diet. We emphasize the need for research that takes into account environmental factors, food web complexity, and nanomaterial diversity, in order to better understand the role of nanomaterials in affecting natural communities as well as human health. *Acknowledgement - This research was supported by Basic Science Research Program through the National Research Foundation of Korea (NRF) funded by the Ministry of Education (2013R1A1A2061386), and the Ministry of Science, ICT and Future Planning (2014R1A2A1A11050513).*

Al2O3 nanoparticles reduce toxic effects of thiacloprid on the non-biting midge Chironomus riparius

C. Lorenz, Universtät Tübingen / Institute of Evolution and Ecology Animal Physiological Ecology; L. Jäger, University of Tuebingen / Animal Physiological

Ecology; L. Guluzada, University of Tuebingen / Center for Applied Geosciences; L. Luo, University of Tuebingen / Institute of Inorganic Chemistry; J. Wicht, University of Tuebingen / Institute of Physical and Theoretical Chemistry; E. Früh, S. Dietz, University of Tuebingen / Institute of Evolution and Ecology JD Botany; C. Huhn, University of Tuebingen / Institute of Physical and Theoretical Chemistry; Y. Liang, Universiy of Tuebingen / Insitute of Inorganic Chemistry; S. Haderlein, University of Tuebingen / Center of Applied Geoscience; H.-. Köhler, University of Tuebingen / Institute of Evolution and Ecology Animal Physiological Ecology
The increasing number of publications in the last years show that nanoparticles become more a topic of high concern in ecotoxicology. This is, on one hand, due to increasing usage of nanomaterials while, on the other hand, little is known about their fate and interactions in the environment. Hence, we wanted to examine, if and how Al_2O_3 nanoparticles interact with the neonicotinoid insecticide thiacloprid. To test this, we measured how toxicity of thiacloprid is altered by Al_2O_3 nanoparticles, based on the mortality rate of the non-biting midge *Chironomus riparius*, a well-established study organism in ecotoxicology. The conducted acute toxicity test with fourth instar larvae of *C. riparius* revealed that Al_2O_3 nanoparticles as single substance had no effect on the mortality rate. However, larvae which were exposed to a mixture of thiacloprid and nanoparticles showed a decreased mortality rate, in relation to larvae that were exposed to thiacloprid solely. This protective effect of the Al_2O_3 nanoparticles was inversely correlated with the applied amount of nanoparticles, with higher concentrations of Al_2O_3 nanoparticles resulting in lower mortality. The underlying mechanisms of these interesting phenomena are still under investigation. Yet, solely sorption of thiacloprid onto nanoparticles (pristine and aged) can be excluded as underlying mechanism. Further research will focus on chemical analyses, histopathology as well as an extendend exposure regime of the larvae, which is based on the OECD guideline 218.

177
Anthracene sorption to TiO2 nanoparticles and bioavailability of UV-activated anthracene by-products in larval zebrafish.
D. Patsiou, F. Liu, Heriot Watt University / School of Life Sciences; M.R. McCoustra, Heriot Watt University / School of Engineering and Physical Sciences; T.F. Fernandes, T. Henry, Heriot-Watt University / School of Life Sciences
Engineered nanoparticles (NPs) can be released into aquatic environments and present a risk of toxicity for aquatic organisms. Among the most commonly used NPs are TiO_2-NPs, and, although these NPs appear to be of minimal toxicity, their potential for photo-activity and sorption to toxic substances are persisting environmental concerns. Several studies have shown sorption of organic compounds to TiO_2-NPs and enhanced toxicity of the co-contaminants. The toxicity of polycyclic aromatic hydrocarbons (PAHs) has been extensively studied and there is information on the toxicity of UV-activated PAHs but the interaction between TiO_2-NPs, PAH sorption, and UV-activation is unknown. The objective of this study was to evaluate sorption of anthracene to TiO_2-NPs by 1) analysis of the preparations with and without UVA irradiance by fluorescence spectroscopy and 2) assessment of changes in expression of target biomarker genes including cytochrome P450 1A (*cyp1A*), DNA repair (*ddb2*), superoxide dismutase (*sod1*) and aryl hydrocarbon receptor 2 (*ahr2*) genes, in larval zebrafish. Zebrafish larvae (72 hpf) were exposed (24 h) to anthracene (0-30 μg/L) in freshwater ([Ca^{2+}] = 71 mg/L according to OECD no. 203). Preparations were exposed to 80 kJ/m^2 UVA at the end of the 24 h exposure, and larvae were sampled at 3 h after UVA exposure. For experiments in which sorption of anthracene to TiO_2-NPs (4-8 nm diameter) was investigated, TiO_2-NPs (2 mg/L) were added to anthracene preparations and stirred for 24 h prior start of exposure. Anthracene was not acutely toxic to zebrafish larvae at the concentrations tested. After the UVA exposure, zebrafish mortality was 28±8% (±SD, n=3) at the highest anthracene concentration (30 μg/L). When fish were exposed to anthracene and UVA, a 45-fold increase in *cyp1A* expression and a 1.7 fold-induction of *sod1* were observed at 15 μg/L anthracene. The presence of 2 mg/L TiO_2-NPs with anthracene resulted in no significant change in expression of either *cyp1A* or *sod1* after UVA exposure compared to unexposed controls. For fish exposed to TiO_2 (2mg/L) and UVA without anthracene there was no induction of either *cyp1A* or *sod1*, which is in accordance with other studies that have also not observed photo-induced toxicity at relatively low TiO_2-NP concentrations. Future work will investigate the association between TiO_2-NPs and PAHs and the products of photo-induction.

178
Influence of multiwalled carbon nanotubes on the toxicity and bioaccumulation of triclocarban in aquatic organisms of different trophic levels
H.M. Maes, M.P. Hennig, RWTH Aachen University / Institute for Environmental Research; N. Siebers, Forschungszentrum Jülich GmbH; S. Rhiem, North Rhine-Westphalia State Environment Agency (LANUV NRW) / Fachbereich; I. Politowski, S. Treidy, V. Jung, L. Deermann, A. Wyrwoll, A. Schaeffer, RWTH Aachen University / Institute for Environmental Research
Although the acute toxicity of MWCNTs is rather low, this nanomaterial was shown to be taken up by different organisms and could therefore influence the bioavailability of environmental pollutants due to its high sorptive capacity. We investigated the sorption of the antibacterial and preservative agent used in personal care products, triclocarban (TCC), to MWCNTs, and the influence of this interaction on the bioavailability of TCC for organisms related to one another in the food chain: the green alga *Desmodesmus subspicatus*, the water flea *Daphia magna*, the brine shrimp *Artemia salina*, and the zebrafish *Danio rerio*. Next to unaltered MWCNTs, the released material of plastic composites, in which MWCNTs were embedded, was tested. It was shown that the presence of MWCNTs protects the polymer matrix from degradation due to simulated solar radiation. However, up to 1% of the embedded CNTs were released from irradiated samples that were transferred to different media, whereas release from non-irradiated control samples was much lower. Both single nanotubes as well as nano- and microscale CNTs-polymer fragments were detected and visualized. Both *D. magna* and *A. salina* were able to take up this material. TCC sorption to MWCNTs was quite high with sorption coefficients ($LogK_{CNT}$) of about 7.5 in all media. This resulted in lower toxicity of TCC to all test organisms when MWCNTs were present in the exposure media. Similarly, higher bioaccumulation factors (BAFs) were obtained when MWCNTs were absent in the media. These results show that MWCNTs lower the bioavailability of TCC to freshwater and saltwater species although this nanomaterial is known to be taken up by these organisms to a relatively large extent. From the elimination experiments with *D. magna* and *A. salina*, it can be derived that excretion of TCC was faster when MWCNTs were present in the media during the uptake phase. Hence, it seems that TCC bound to MWCNTs is hindered from passing the gut epithelium. Currently, biomagnification experiments are performed in order to evaluate the importance of food chain transfer of MWCNTs, TCC, and TCC-CNTs complexes. Moreover, it will be determined whether the organic compound and the nanomaterial are distributed to different organs and tissues of fish after dietary exposure.

Microplastics in the environment: Sources, Fate and Effects (IV)

179
On the potential role of phytoplankton aggregates in microplastic sedimentation
M. Long, LEMAR UMR 6539 CNRS; B. Moriceau, M. Gallinari, LEMAR UMR 6539 CNRS/Ifremer/IRD/UBO; C. Lambert, LEMAR UMR 6539 CNRS/UBO/IRD/Ifremer; A. Huvet, Ifremer, LEMAR UMR 6539 CNRS/UBO/IRD/Ifremer; I. Paul-Pont, LEMAR UMR 6539 CNRS/UBO/IRD/Ifremer; H. Hégaret, LEMAR UMR 6539 CNRS/UBO/IRD/Ifremer / UMR CNRS Ifremer IRD UBO; P. Soudant, LEMAR UMR 6539 CNRS/UBO/IRD/Ifremer
Microplastics (MPs) pollution is now a major concern in ecotoxicological topics. To better assess the impact of MPs on marine environment, scientists need to understand MPs cycle. Recent estimations of small size MPs concentrations at the surface layer of the oceans were lower than model-predicted estimations based on larger plastic wastes. Different sinks were suggested to explain this mismatch including physical mechanisms and interactions with marine organisms. Among marine organisms, phytoplankton may have a role in MPs distribution. In this experiment, we studied the possibility for phytoplankton aggregates to bind and incorporate MPs through their sedimentation. At the same time we investigated the respective impacts of MPs on aggregate parameters and the impacts of aggregates on MPs sink. Three types of phytoplankton aggregates (*Chaetoceros* neogracile aggregates, *Rhodomonas salina* aggregates and a mix of the two species) were produced in a roller-tank. These aggregates were exposed to a flow (680 mL per hour) of 2 μm microbeads of polystyrene (yellow-green fluorescent, 1.050 kg L^{-1}, 10^4 beads mL^{-1}) in a roller tank that mimic aggregates sink. After exposure, aggregate parameters were assessed like size, permeability, excess density, sinking rates and MPs content. Diatom aggregates were on average bigger, stronger, stickier and sunk faster than the aggregates made from *R. salina* or from the mix of microalgae. After MPs exposure, all laboratory-made aggregates incorporated MPs. The smaller and more fragile aggregates from *R. salina* incorporated more MPs than *C. neogracile* and mix aggregates. When incorporated into aggregates, sinking rates of MPs increased from tenths to several hundred meters per day. Simultaneously aggregates sinking rates was impacted. Sinking rates of *C. neogracile* aggregates strongly decreased while sinking rates of *R. salina* increased. This study demonstrated that MPs can be incorporated through aggregates during their settling in the water column, and that the efficiency depends on the composition of marine aggregates. A new pathway was highlighted for MPs sink that may partially explain the lack of MPs in surface layer. Even though further studies are needed with different laboratory-made aggregates or field sampled aggregates to better assess the potential for marine snow to aggregate MPs. In parallel, *in-situ* quantification of MPs in marine snow from should be done to address the relevance of this process in MPs cycle.

Aquatic ecotoxicity testing of nanoplastics - lessons learned from nanoecotoxicology

N.B. Hartmann, Technical University of Denmark (DTU) / DTU Environment; L. Skjolding, DTU / DTU Environment; T. Nolte, Radboud University Nijmegen / Department of Environmental Science; A. Baun, DTU Environment / Department of Environmental Engineering
Micron-sized particles have so far been the main research focus in regard to aquatic plastic particle pollution. Due to mesh netting sizes, nanoplastics are not detected in commonly used methods for plastic pollution surveys. Nonetheless, nanoplastics are likely to be pervasive in the aquatic environment. Here, as for microplastics, nanoplastics may cause direct ecotoxic effects and carrier-effects through adsorption of co-contaminants and the smaller particle size could be an influential factor. However, actual knowledge is currently limited to a few scientific studies. Based on literature information, combined with our own previous work on nano- and microplastics as well as test method development and adaptation for ecotoxicity testing of engineered nanomaterials, we here present an overview of lessons learned from nanoecotoxicology. We offer suggestions on how these can be transferred into recommendations for ecotoxicity testing of nano(and micro)plastics. In addition we suggest how to implement some of these recommendations in algae growth inhibition tests, studies of carrier-potential of nanoplastics and uptake in aquatic invertebrates and fish.

181
Effects of ingested PVC micro particles with and without sorbed benzo(a)pyrene on the cellular and sub cellular processes of the macrobenthic organism Hediste diversicolor
A. Gomiero, International Research Institute of Stavanger / Enviromnent; L. Kozinkova, CIBM; P. Strafella, National Reseach Council of Italy / Institute of Marine Science; G. Bruno, G. Fabi, National Research Council of Italy / Institute of Marine Sciences
Along with impacts such as global warming, ocean acidification and habitat destruction, pollution can cause undesirable changes in marine ecosystems. In the last decade, plastic pollution has been a matter of increasing scientific and public concern. Marine debris is comprised primarily of non-biodegradable plastic polymers and it is considered a multiple stressor in aquatic habitats as a consequence of the large mixture of chemical contaminants potentially adsorbed from the aquatic environment and/or associated with it in the polymer production. Polymers with densities higher than seawater (i.e., PVC) tend to sink and continuously accumulate in sediments. Animals from sedimentary habitats are therefore vulnerable as microplastic particles may adsorb organic pollutants from the aquatic environment and be largely accumulated in sediments. In laboratory conditions, microplastics have been shown to be ingested by amphipods, barnacles, mussels and lugworms [1]. However, the available data concerning the effects of microplastic particles is limited and even less is known concerning the “Trojan horse” effect caused by microplastics contaminated with ubiquitous and highly toxic environmental contaminants such as PAHs. Thus, the current study focused on the acute effects of the combined exposure to microplastics and benzo(a)pyrene sorbed particles on the macrobenthonic model organisms *Hediste diversicolor*, a species with a relevant role in trophic webs.

182
A trophic food web experiment with Artemia nauplii and zebrafish (Danio rerio) for the transfer of microplastics and associated POPs
A. Batel, COS University of Heidelberg / Aquatic Ecology and Toxicology; M. Scherer, University of Heidelberg; F. Linti, COS University of Heidelberg; T. Braunbeck, University of Heidelberg / Centre for Organismal Studies
In the present study, a simple artificial food chain with *Artemia* spec. nauplii and zebrafish (*Danio rerio*) was established to analyze the transfer of microplastic particles and associated persistent organic pollutants (POPs) between different trophic levels. The uptake of microplastic particles and the transfer of potential harmful substances along with microplastics has been studied in a variety of organisms, especially invertebrates. However, the potential accumulation of very small microplastic particles along food webs ending with vertebrate models has not been studied so far. *Artemia* nauplii and zebrafish were exposed to very small (1 - 20 μm) microplastic particles, which accumulated within nauplii and were subsequently transferred to fish. For the analyses of the transfer of POPs *via* microplastics, the polycyclic aromatic hydrocarbon (PAH) benzo[a]pyrene (BaP) was used since (a) it is a common POP also found on environmental microplastics and (b) it shows autofluorescence at respective wavelengths. Virgin particles not loaded with BaP did not cause any observable physical harm in the intestinal tracts of zebrafish. The visual fluorescence tracking of BaP was strong enough to detect the transfer and accumulation of BaP both in *Artemia* nauplii and zebrafish intestines. This indicates that food-borne microplastic-associated POPs do desorb in the intestine of fish and are thus transferred to the intestinal epithelium and liver of higher organisms. However, further research is needed on different spectra analyses and metabolization of microplastic-associated POPs.

183
Does microplastic in recycled organic resources pose a risk to terrestrial environments?
A. Palmqvist, Roskilde University / Department of Environmental Social and Spatial Change; J. Magid, University of Copenhagen / Department of Plant and Environmental Sciences; K. Syberg, Roskilde University / Department of Environmental Social and Spatial Change
Problems related to plastic litter pollution have been recognised since early 1970’s, and in recent years microplastic (MP) contamination of particularly the marine environment has been subject to increased focus. Although a number of publications in the last couple of years have pinpointed that also freshwater systems may be at risk from MPs, mainly due to release of particles from waste-water (WW) treatment processes, MP contamination of terrestrial environments has up until now rarely been studied. Due to processes taking place in WW treatment plants, a large proportion of particles in WW is likely to settle out in the sludge together with organic material. This reduces the amount of MPs in the effluent water and consequently contamination of aquatic environments. However, when sludge resulting from WW treatment processes is used for soil amendment, in order to recycle phosphate for agricultural purposes, deposited plastics are added to the terrestrial environment. Because plastic is slowly broken down it may accumulate in soils. To assess potential risk of MPs in terrestrial environments it is necessary to increase knowledge on type and amount of MPs in organic resources as well as in recipient soils. At the same time studies of potential effects of MP to soil organisms is largely absent from the scientific literature. In this presentation we give an introduction to what we currently know about potential exposure in terrestrial environments, including some recent studies from our lab on type and amount of MPs in Danish WW sludge and soils fertilised with different organic resources. These studies confirm the presence of MPs in both sludge and soils fertilised with sludge or composted household waste. We also include preliminary information on hazard of MPs in terrestrial environments, based on recent experiments on epigeic earthworms, studying the effects of MPs alone and in combination with other environmentally relevant contaminants. The first studies showed limited effects of MPs on earthworms, which however may be due to the employed exposure scenario. Results will be compared to on-going studies with a modified exposure scenario. Although studies so far suggest that MPs will end up in the terrestrial environment, knowledge on hazard of MPs for terrestrial organisms is currently limited as are more ecologically relevant exposure predictions. Therefore more knowledge is required to realistically assess the risk of MPs in terrestrial environments.

184
Be positive or negative? Long-term toxicity of polystyrene nanoparticles to marine planktonic species
e. bergami, University of Siena / Physical Earth and Environmental Sciences; S. Pugnalini, University of Siena / Department of Physical Earth and Environmental Sciences; C. Faleri, University of Siena / Department of Life Sciences; L. Manfra, Institute for Environmental Protection and Research; K.A. Dawson, University College Dublin / Centre for BioNano Interaction School of Chemistry and Chemical Biology; I. Corsi, University of Siena / Department of Physical Earth and Environmental Sciences
Micro as well as nanoplastics have been identified by the international community as one of the greatest challenges for marine ecosystems worldwide. Concerning the nano-sized debris (< 1 μm), their occurrence in the environment has not been quantified yet, due to current standardized methods for sampling as well as identification by analytical techniques. Polystyrene nanoparticles (PS NPs) have been recently adopted as model for nanoplastics in short-term ecotoxicological studies, but data concerning long-term toxicity on marine organisms are still lacking. Here we report the effects of nanoplastics to two marine planktonic species as green microalga *Dunaliella tertiolecta* and brine shrimp *Artemia franciscana*, exposed to anionic carboxylated (PS-COOH) and cationic amino (PS-NH_2) PS NPs. Since aggregation and surface charges can be key factors driving the eco-interactions of nanoplastics in the marine environment, their behaviour was assessed by DLS in both natural sea water (NSW) and algal medium (AM) as well as the formation of an eco-corona investigated. In terms of ecotoxicity, PS-COOH did not affect the growth of marine algae (72 h) and brine shrimps (14 d) up to 25 μg/ml and 10 μg/ml respectively but high retention of PS-COOH aggregates was observed in the digestive tract of brine shrimps at 14 days. On the opposite, PS-NH_2 caused high mortality of brine shrimps (LC_{50} 0.83 μg/ml, 14 days) as well as inhibition of algal growth and alterations (at 5 μg/ml) in the microalgae plasma membrane respect to the control group. These results represent a first insight into nanoplastics long-term toxicity to marine planktonic species underlining the role of nanoplastics surface charge in agreement with previous findings on other invertebrate marine species. This study emphasizes that long-term exposure constitutes a valid tool to assess the ecotoxicity of emerging contaminants including nanoplastics.

State of the science on poly- and perfluoroalkyl substances (PFASs) in the environment and humans (I)

185
Characterizing spatiotemporal pattern of global PFAS releases using a dynamic substance flow analysis model
L. Li, Peking University / College of Environmental Science and Engineering; J. Liu, Peking University

This work developed a dynamic substance flow analysis (DSFA) model to imitate the temporal evolution and spatial shift of global environmental releases of homologous fluorotelomers and perfluorocarboxylic acids from both lifecycle and end-of-life stages. Major findings include: (i) The temporal pattern is illustrated by the evolution of environmental releases of PFOA and 8:2FTOH in China. Our DSFA results show that industrial processes are predominant sources to PFOA releases, therefore the scheduled phase-out of PFOA is anticipated to nearly eliminate future PFOA releases, while industrial processes and end-of-life disposal have almost equal contributions to 8:2FTOH releases. The time course of environmental releases of 8:2FTOH exhibit two sequential peaks a ~10-year gap, which indicates that end-of-life emissions from waste stocks will be noticeable sources in the future. (ii) The spatial pattern is demonstrated using snapshots of geographical distribution of global PFOA and 8:2FTOH emission hotspots for 1995, 2010 and 2020. The emission hotspot of PFOA shifted from Europe and North America in 1995 to China in 2010. The evolution of 8:2FTOH emissions in China resembles that in Europe and North America but with a ~10-year delay. This delay means that the West Pacific would become a remaining dominant source region in 2020 if no appropriate end-of-life managements are implemented. Our case highlights the implication and importance of the DSFA in future risk management of PFASs. Based on our DSFA-derived emission estimates, scientists are able to appraise the performances of future end-of-life management options and assess the impacts of the geographical shift of emissions on environment and human.

Assessing the temporal shift of concentrations of perfluorooctane sulfonic acid (PFOS) in the environment following industrial transition

J. Boucher, ETH Zurich; Z. Wang, Swiss Federal institute of Technology / Institute for Chemical and Bioengeneering; M. Scheringer, ETH Zurich / Institute for Chemical and Bioengineering; I. Cousins, Stockholm University / Department of Environmental Science and Analytical Chemistry ACES; K. Hungerbuehler, ETH Zurich / Institute for Chemical and Bioengineering

Long-chain perfluoroalkane sulfonic acids (PFSAs), including perfluorooctane sulfonic acid (PFOS), are a group of chemicals that have been widely used since the late 1950s. These substances are highly persistent, bioaccumulative, toxic and are distributed ubiquitously in the environment, biota and humans. In 2009, Paul et al. and Armitage et al. estimated the global emissions of PFOS in 1970–2012 and in 1957–2030, respectively. Armitage et al. coupled their emission inventory model to a global-scale multimedia mass-balance model to assess the global fate and transport of PFOS and PFOS precursors (PreFOS). However, they note that their modeled atmospheric PreFOS concentrations were too low by one to two orders of magnitude compared to measured concentrations. Furthermore, there has been an ongoing global industrial transition that was not fully characterized in previous studies. The year 2000 was the start of a voluntarily phase out and regulatory restrictions of PFOS production and use in western countries. In contrast, manufacturers in China have reported large increases in their production. Increased use of PreFOS based insecticides in Brazil and neighboring countries has also taken place. In this study, we redesign and establish a new global emissions inventory of PFOS and PreFOS based on up to date information. We estimate between 1400-8400 tonnes and 2200-4100 tonnes of PreFOS and PFOS, respectively, to have been emitted between 1958 and 2015. These results are higher than those estimated by Armitage et al. (735-4005 tonnes PreFOS and 285-2565 tonnes PFOS) due to consideration of more detailed manufacturing emissions data, direct use of PreFOS as ingredients in products, and the degradation of complex molecular substances into PreFOS. To get an improved overview of transport and fate in the environment during this transition period, we combine this new inventory with a global-scale multimedia mass-balance model to derive environmental concentrations that we then compare to measured concentrations. A decline following the industrial transition period is visible within two to three years in the atmospheric concentrations of xFOSAs and xFOSEs, whereas a longer delay of five to six years exists before an impact is seen on the modeled PFOS concentrations in oceans.

187

Levels of perfluoroalkyl substances in global air from 3 years of sampling under the Global Atmospheric Passive Sampling (GAPS) Network

C. Rauert, Environment Canada / Air Quality Processes Research Section; L. Ahrens, Swedish University of Agricultural Sciences (SLU) / Dept of Aquatic Sciences and Assessment; J. Schuster; M.E. Shoeib, Environment Canada / Atmospheric Science and Technology Directorate; T. Harner, Environment Canada / Atmospheric Science Technology Directorate

Poly- and perfluoroalkyl substances (PFASs) have been used globally with commercial and industrial applications that include oil and water repelants, and film-forming fire fighting foams. Perfluorooctane sulfonic acid (PFOS) is of particular interest as it is a priority chemical under the United Nations Environment Program (UNEP) Stockholm Convention for Persistent Organic Pollutants (POPs). The Global Atmospheric Passive Sampling (GAPS) Network monitors priority chemicals at over 50 global sites, and is the only global-scale air surveillance network measuring PFASs in air. PFASs were monitored at GAPS sites using Sorbent Impregnated Polyurethane Foam (SIP) disk passive air samplers (PAS) during three sampling years, to determine spatial and temporal trends of PFASs in global air. The data presented here shows the first global air comparison of PFASs, using SIP disk PAS samplers. Perfluorobutanoic acid (PFBA) had the highest concentrations in all samples (3) and was detected at almost every site sampled during the 3 campaigns. Temporal trends were not seen for any PFAS in sampled sites and spatial trends were not observed for any of the perfluorosulfonic acids. However, PFBA showed evidence of reduced levels at Asia and African sampling sites as compared to levels seen in Europe and Central/North America. PFOS had the highest concentrations of the sulfonic acids (3) and a reduction in global air concentrations of this chemical due to the phase out of PFOS in 2009 is not yet in evidence.

188

Effects of weathering on PFASs used in durable water repellence of textiles

I.v. Veen, Institute for Environmental Studies (IVM) VU University Amsterdam / Chemistry and Biology; A. Hanning, Swerea IVF AB; J. Weiss, Stockholm University / Department of Environmental Science and Analytical Chemistry ACES; P. Leonards, VU University, Institute for Environmental Studies / Institute for Environmental Studies IVM

Per- and polyfluoroalkyl substances (PFASs) are used in textiles for their oil and water repellent properties. Because PFASs with long perfluorinated chains have been shown to be persistent in the environment, bioaccumulative and (eco)toxic, the textile industry is phasing-out the long-chain PFASs and is replacing those compounds with alternative chemistries to deliver the desired durable water and soil repellent (DWR) effect. Those alternative chemistries can be divided in three main groups: fluorocarbon-based, silicon-based and hydrocarbon-based polymers. In the SUPFES (Substitution in practice of prioritised fluorinated compounds for textile applications) project the alternative DWRs are assessed to (i) their structural properties and connected performance, (ii) loss and degradation processes resulting in diffuse environmental emissions, and (iii) hazard profile for the emitted substances. As part of SUPFES weathering experiments are performed with textiles from outdoor clothing which are exposed to elevated UV radiation, humidity, and temperature in an aging device for 300 h, which is equivalent to the life time of the outdoor clothing. Before and after aging of the samples, the textiles were analysed for their perfluoroalkyl acid (PFAA) content. Results showed that weather conditions, like sunlight, high temperature, or humidity have an effect on PFASs used in DWR of outdoor clothing. Concentration of PFAAs increased, and PFAAs not present in the original textiles were formed during exposure to weather conditions. More research is needed to clarify the origin of the PFAAs and to determine the transformation route.

189

Investigation on the presence and behaviour of precursors to perfluorinated compounds in the environment

C. Gremmel, I. Dimzon, Hochschule Fresenius, University of Applied Sciences; P. de Voogt, University of Amsterdam / IBED; T. Frömel, T.P. Knepper, Hochschule Fresenius, University of Applied Sciences

Wastewater treatment plants (WWTPs) have been identified as a significant pathway for the introduction perfluoroalkyl and polyfluoroalkyl substances (PFASs) to natural waters. In several studies it was observed that the concentration of certain PFASs were higher in the WWTP effluent compared to the corresponding influent. One reason for this might be the biotransformation of precursor substances, which were converted into known and analysed PFASs. The objective of the present study was the identification of potential precursor substances of persistent PFASs in WWTPs. Following the development of robust and validated analytical methods 65 PFASs, which included persistent PFASs and their potential precursors, sampling campaigns in six WWTPs (industrial and municipal, located in Europe) over a period of four weeks each were realised. The influent water and the effluent water, the air above the influent and the sludge of the WWTPs were sampled and analysed. Several transformation products of fluorotelomer alcohols (FTOHs) e.g. the unsaturated fluorotelomer carboxylic acids (FTUCAs), fluorotelomer carboxylic acids (FTCAs) and the x:3-acids could be determined, particularly in the aqueous phase of the industrial WWTPs. The further biotransformation of these intermediates led to an increased concentration of perfluoroalkyl carboxylic acids (PFCAs) in the effluent of WWTPs. Based on the frequency of detection and concentration of FTOHs, biotransformation intermediates (e.g. FTUCAs and FTCAs) and persistent biotransformation products, fluorotelomer-based precursors were identified as the most relevant precursors of PFCAs. Data for several corresponding WWTP influent, air and effluent samples suggests that FTOHs could be present as a residual synthetic intermediate of non-targeted PFASs, such as fluorinated polymers or other unknown low molecular weight fluorotelomer-based chemicals, which might be a further reason for the high frequency of detection. This should be investigated in future studies.

190

Perfluorinated alkyl substances (PFASs) in household dust in Central Europe and North America

P. Karaskova, Masaryk University; M. Venier, Indiana University / SPEA; J. Becanova, . Vojta, L. Melymuk, R. Prokes, Masaryk University / RECETOX

Research Centre for Toxic Compounds in the Environment; K. Romanak, Indiana University; J.O. Okeme, University of Toronto / Physical and Environmental Sciences; A. Saini, University of Toronto / Department of Physical and Environmental Sciences; M.L. Diamond, University of Toronto / Department of Earth Sciences; J. Klanova, Masaryk University / RECETOX Research Centre for Toxic Compounds in the Environment

In everyday life we come into contact with various chemical substances contained in consumer products. Perfluorinated alkyl compounds (PFASs) are one of the largest groups of such chemicals. PFASs have been used in a variety of applications such as surfactants, lubricants, in paper and textile coatings, polishes, food packaging, and fire-fighting foams for more than 60 years. They are added to consumer products to make them resistant to water, oil, stains and even fire. They are persistent, bioaccumulative and they have become ubiquitous. Several exposure pathways for PFASs have been identified: food and drinking water are the most important ones, followed by dust ingestion and indoor air. Humans spend almost 90% of their time indoors and moreover children mostly play on the floor, and hand-to-mouth activity is more significant than for adults. This can lead to higher exposure to PFASs than for adults. This work is part of a larger study within the Czech-American Scientific Cooperation Program aimed at identifying levels of contamination in residential indoor environments from three countries (Czech Republic, Canada and USA). The aim of the present study was to investigate and compare indoor concentrations of twenty PFASs in house dust samples collected in living rooms and bedrooms in 2013 from more than 30 homes of volunteers in these three countries. We also looked at differences between countries and compound patterns. Several PFASs were found in dust samples from more than 50 homes from three countries. Concentrations are of the same order of magnitude as in previous studies. Slightly significant differences were observed between samples from North America and Czech Republic. The dominant contaminant in all countries was PFOS but eight out of 20 target PFASs were detected in more than 50 percent of the samples. Among the carboxylic acids, PFHxA is a major contaminant in Czech samples while in North America PFOA showed the highest concentration. Spearman rank correlation gave good correlations between PFOA and shorter-chain carboxylic acids, suggesting that short-chain PFCAs are in use but still do not replace PFOA.

Interpreting Biological Effects of Metals and Their Mixtures

191

Metals in the aquatic environment - interactions and implications for the speciation and bioavailability

M.F. Benedetti, Université Paris Diderot; A. Gelabert, IPGP; Y. Sivry, IPGP - VAT FR79197534282; R.F. Domingos, Institut de Physique du Globe de Paris / Équipe de Géochimie des Eaux

In most case scenarios, individual metals exist as components in mixtures with organic and inorganic substances and/or particulate matter. While the concepts encompassing mixture toxicity and modeling have been around for decades, only recently have new approaches (dynamic speciation techniques and fate and bioavailability models) been expanded to consider metal mixture scenarios. For example, the kinetic features of humic substances and inorganic colloids on the complexation of metals are generally considered. Although current environmental regulations rarely require an assessment of chemicals mixtures, research on these mixtures in the environment is essential for future regulatory demands and is vital for ensuring adequate environmental protection. Interpretation of speciation and bioavailability data from metal mixtures can be very complex and demanding, due to the existence of kinetic physicochemical transformations of the dynamic components. This kinetic effect largely affects metals' dynamic speciation, culminating in different transformed metal-containing products with different contributions for the metal uptake by a consuming interface. The environmental fate of metal mixtures, which determines how the mixture is biogeochemically processed and which receptors are most exposed (organisms and exposure route), with a special focus on their dynamic speciation, including a critical evaluation of the current challenges and available dynamic speciation techniques as well as computer codes and models, will be discussed.

192

Chronic metal mixture toxicity to Ceriodaphnia dubia can be predicted using an independent action based bioavailability model

C. Nys, University of Ghent / Laboratory for Environmental Toxicology and Aquatic Ecology GhEnToxLab unit; C. Janssen, University of Ghent / Laboratory of Environmental Toxicology and Aquatic Ecology GhEnToxLab unit; K. De Schamphelaere, Ghent University (UGent) / Laboratory for Environmental Toxicology and Aquatic Ecology GhEnToxLab unit

Recently, several bioavailability-based models have been shown to predict acute metal mixture toxicity with reasonable accuracy. However, the application of such models to chronic mixture toxicity is less well established. In this study, we developed a chronic metal mixture bioavailability model (MMBM) by combining the existing chronic daphnidbioavailability models for the individual metals with the independent action model. The MMBM assumed that each metals binds to its own biotic ligand (BL) site and that metal (mixture) toxicity is related to the concentration of free metal ion binding to its metal-specific BL. Additionally, based on previous toxicity testing with Ni, Zn, and Pb mixtures, we assumed that Ni^{2+}, Zn^{2+} and Pb^{2+} do not compete for binding at the biotic ligand sites. To evaluate the predictive capacity of the MMBM, we investigated the chronic toxicity of a Ni-Zn-Pb mixture to *Ceriodaphnia dubia* in 6 (modified) natural waters differing in pH, Ca, and/or dissolved organic carbon (DOC) (pH range: 7-8; Ca range: 1-2 mM; DOC range: 5-12 mg/L). The toxicity of the Ni-Zn-Pb mixture was assessed concurrently with that of the individual metals. The predictive capacities of the chronic MMBM for mixtures was evaluated relative to that of the MMBM for the individual metals. Dissolved metal toxicity in the individual metal treatments, expressed as 7d-EC50, varied 4.3-fold, 3.3-fold, and 2.7-fold for Zn, Ni, and Pb depending on the water chemistry, respectively. The MMBM predicted the relative reproduction of 85% of the mixture treatments within 20% error, while the relative reproduction in the individual Zn, Ni, and Pb exposures were predicted within 20% error for 73, 83, and 70, respectively. This indicates that the MMBM predicted chronic toxicity of the ternary Ni-Zn-Pb mixture at least equally accurate as the observed in the individual metal treatments. Based on our study chronic MMBMs are a promising tool to account for the effects of water chemistry on metal mixtures during chronic exposure and could be used in metal risk assessment frameworks.

193

Uptake and toxicity of copper and cadmium in single and mixtures exposure in the zebrafish, Danio rerio

K.I. Cordery, Universiteit Antwerpen / Biology; S. Husson, Systemic Physiological and Ecotoxicological Research group - University of Antwerp; E.E. Smolders, Katholieke Universiteit Leuven / Division Soil and Water Management; K. De Schamphelaere, Ghent University (UGent) / Laboratory for Environmental Toxicology and Aquatic Ecology GhEnToxLab unit; R. Blust, Department of Biology

The aquatic environment receives a wide range of pollutants from a number of sources and is highly impacted by pollution. Due to the simultaneous presence of numerous pollutants it is important to investigate the effects of co-contamination. It has been shown that the presence of contaminants in mixtures can lead to a change in the effects of the individual contaminants resulting in synergistic or antagonistic toxicological effects on organisms. In this study we have investigated the uptake and toxicity (mortality) of copper (Cu) and cadmium (Cd) in adult zebrafish (*Danio rerio*) on the basis of 10-day and 28-day exposure experiments under different water hardness regimes. The experiments were conducted according to a partial factorial design covering a wide range of exposure concentrations. Survival and whole body metal and major cation concentrations were measured in all fish to determine whether Cu and Cd accumulation showed interactive effects and metal body burdens were predictive of toxicity. The levels of major cations were measured to determine whether loss of ion regulatory capacity was predictive of toxicity in the different single and mixture exposure scenarios. In the single metal exposures the zebrafish were generally much more sensitive to Cu than to Cd and the toxic effects showed a strong dependence on water chemistry. Exposure of the fish to binary mixtures of the metals resulted in a very strong synergisms when compared to the mixture toxicity predictions computed with the concentration addition (CA) model using the 10-day EC_{10} values for each of the metals. Toxicity also strongly increased with decreasing water hardness in the single exposures and the interactive effect between the two metals was observed at each of the water hardnesses tested. Neither the body burden nor the uptake rate of individual and mixture exposures explain the mortality observed in the different scenarios. An analysis of the major cation profiles showed that a significant loss of ions, in particular Na, has a large impact on the observed mortality.

Departures from additivity in a wastewater sample spiked with binary mixtures of heavy metals

k.m. betancor, F. Fernandez-Piñas, F. Leganes-Nieto, Universidad Autónoma de Madrid / Biology; I. Rodea-Palomares, University of Florida / IFAS / Agricultural Biological Engineering

Due to the well-known toxicity of heavy metals, monitoring and regulation of their concentration in the environment has been a very important issue in the past years. There are many methods for heavy metals detection based on physical and chemical techniques, however, such methods are not able to distinguish between available and non-available fractions of metals existing in the environment. In contrast to chemical methods, whole-cell bioreporters measure the bioavailable fraction of these analytes. Recently, we have mathematically developed a novel additivity framework for mixture research in the context of whole cell inducible biosensors [1].This new method is based on Concentration Addition (CA), also called Loewe Additivity. Our new approach proposes a multivariate extension of the effective dose (EDp) to take into account the occurrence of differential maximal effects presented by the mixture components, and also, an extension of Loewe Additivity that enables its direct application in a biphasic dose-response framework. Moreover, this method proposes a two-dimensional formulation of Loewe additivity computed for the two components of EDp, dose (*D*) and effect (*E*). The analyses of departures from additivity are based on Combination Index (CI) [2] for the *D* and *E* dimensions, where, $CI_{D\ or}\ CI_{E}D$ orCI_{E}=1 indicates additivity effect and CI_D or $CI_E > 1$ indicates antagonism. For global assessment of departures from additivity, a simplification of the two-dimensional information can be obtained by calculating a weighted index CI_w for any fractional effect *p*: $CI_w = CI_D \cdot CI_E$, where $CI_w > 1$ indicates overall antagonism, $CI_w = 1$ an overall additive effect, and CI_w [1] Martin K *et al*. Effect of temperature on Ni bioaccumulation and chronic toxicity to Daphnia magna

C.S. Pereira, GhEnToxLab; C. Janssen, University of Ghent / Laboratory of Environmental Toxicology and Aquatic Ecology GhEnToxLab unit; R. Blust, Department of Biology; K. De Schamphelaere, Ghent University (UGent) / Laboratory for Environmental Toxicology and Aquatic Ecology GhEnToxLab unit

The mechanisms involved in nickel toxicity are not fully understood. No information is available about the effect of temperature on chronic nickel toxicity to *Daphnia*. Therefore, our first objective was to investigate the effect of temperature on chronic nickel (Ni) toxicity and if a different effect is observed among four *Daphnia magna* clones. The second objective was to understand how temperature affects Ni uptake and elimination in four *D. magna* clones. At 15, 20 and 25°C 21-day life table experiments with Ni were performed with four *D. magna* clones taken from the same natural population. A linear model was built to predict the Ni effect on the reproduction per individual female(R_0) as function of temperature and clone. The effect concentrations (21 d EC_x) and concentration response curves were calculated for R_0 of all clones (to mimicked the effects on a population). Effect concentrations of the individual clones were also calculated. Uptake experiment was performed with the four *D. magna* clones exposed to 70 μg Ni.L^{-1} at 15, 20 and 25°C. Organisms were exposed to the stable isotope ^{62}Ni during 48h. The linear model built indicate that the effect of nickel on reproduction per individual female (R_0) was significantly affected by temperature and that this effect depended on the clone. The 21 d EC_{50}s based on R_0 of all clones (to mimicked a population) tested at 15, 20 and 25°C were 59.2, 74.3 and 121.2 μg Ni.L^{-1}, respectively. This represents a two-fold variation on the 21 d EC_{50}s. Significant interactions were detected between temperature, nickel and clones. After 48h of exposure nickel concentrations in Daphnids were lower at 25°C than at 15 or 20°C. No significant correlation was observed between 21 d EC_{50} and nickel accumulation after 48h of exposure. This suggests that it is not only the internal body concentration determines' the effect of temperature on Ni toxicity but that effect of temperature on the internal sequestration or toxicodynamics processes may also play a role in nickel toxicity. The results of the present study are in contrast with previous acute studies which indicate that acute metal toxicity increases with increasing temperatures. Additionally, on average chronic nickel toxicity decreased at higher temperatures. The present study showed that chronic nickel toxicity was significantly affected by temperature and this effect was different among the four *D. magna* clones tested.

Fishing for mixture effects: impacts of diclofenac and cadmium on oxidative stress in a threatened indigenous fish species

N. McRae, University of Canterbury / School of Biological Sciences; S.K. Gaw, University of Canterbury / Chemistry; B.W. Brooks, Baylor University / Environmental Health Science Program Department of Environmental Science; C.N. Glover, Athabasca University

Pharmaceuticals and trace metals are increasingly prevalent in the aquatic environment due to anthropogenic pressures such as population increases. Although present at low concentrations, environmental persistence and high bioactivity of these chemicals can result in toxicological impacts on non-target biota. There is however, very little understanding of how emerging contaminants, such as pharmaceuticals interact with other toxicants. This study aimed to investigate the toxic impacts that occur when a native New Zealand fish, inanga (*Galaxias maculatus*), is exposed to mixtures of an emerging pharmaceutical contaminant, diclofenac (DCF), and a trace metal, cadmium (Cd). Inanga inhabits near-coastal freshwaters, and migrate through estuaries. As result they are potentially exposed to water bodies where toxicants are most concentrated. In laboratory studies, inanga were exposed to DCF (1000 µg L^{-1}), Cd (10 µg L^{-1}) and their mixtures (DCF, 1000 µg L^{-1}; Cd, 10 µg L^{-1}) for 96 h. The sublethal effects on hepatic oxidative stress were examined by measuring oxidative damage (lipid peroxidation) and antioxidant defence (catalase). There was a significant increase in hepatic catalase activity in fish exposed to Cd (10 µg L^{-1}) alone. However the increase in this important anti-oxidant defence enzyme was not sufficient to prevent an increase in lipid peroxidation, which also increased significantly relative to the unexposed control. Fish exposed to the Cd (10 µg L^{-1}) and DCF (1000 µg L^{-1}) mixture exhibited a different response whereby lipid peroxidation decreased compared to the individual Cd exposure. These results indicate that DCF is protective against metal-induced oxidative damage. These are the first such data to investigate the toxic effects of DCF and metal mixtures on fish. Understanding the impacts of toxicant mixtures, and the mechanisms by which they modify toxicity, is a critical need for the development of realistic environmental regulations.

Interactive effects of climate change and contaminants: environmental risks and human health implications

The impacts of pharmaceutical drugs under ocean acidification: new data on single and combined chronic effects of Carbamazepine on Scrobicularia plana

R. Freitas, Universidade de Aveiro, Portugal / Departamento de Biologia CESAM; A. Almeida, Universidade de Aveiro / Biology Department and CESAM; V. Calisto, Aveiro University / Chemistry Department and CESAM; C.V. Silva; A. Moreira, Aveiro University / Biology Department and CESAM; R. Schneider, BAM Federal Institute for Materials Research and Testing / Dept of Analytical Chemistry Reference Materials; V. Esteves, CESAM Universidade de Aveiro; F.J. Wrona, University of Victoria / Department of Geography University of Victoria National Water Research Institute; E. Figueira, CESAM University of Aveiro; A.M. Soares, Universidade de Aveiro / Department of Biology and CESAM

Ocean acidification (due to increased oceanic CO_2 uptake from atmosphere) and increasing discharges of pharmaceutical drugs, such as carbamazepine (CBZ), an antiepileptic, into the aquatic environment can exert toxic effects on marine organisms, including bivalves. However, the impacts of pH and CBZ when combined are poorly studied. Thus, the present study evaluated the chronic effects (28 days) of an environmental concentration of CBZ (3 μg/L) and the decrease of pH (to 7.1) acting alone and in combination on the marine clam *Scrobicularia plana*. CBZ quantification based on ELISA, protein content (PROT), electron transport activity (ET), lipid peroxidation (LPO) levels, glutathione S-transferase (GSTs), superoxide dismutase (SOD) and catalase (CAT) activities were determined. The mortality results indicated that a 28 days exposure to low pH (7.1) led to lower mortality (22%) than the exposure to single CBZ or the combination of CBZ and pH (33% for each) and that in individuals exposed to low pH mortality was recorded up to the first 96 h of exposure. This indicates an adaptive response of clams to the low pH (7.1), possibly due to changes in acid-base homeostasis, through an increase in the H^+ concentration. The exposure to CBZ led to an increase in Na^+ concentration, affecting the cellular acid-base homeostasis and resulting in higher mortality in clams exposed to CBZ and CBZ + pH. PROT increased after the exposure to CBZ and pH, single or combined, possibly indicating a higher rate of enzyme synthesis to prevent oxidative damage. The increase of GSTs activity under all exposure concentrations may be a consequence of that. ET decreased after all exposure conditions, revealing a lower metabolic rate as a defense mechanism to prevent the damage induced by these stressors. LPO results indicated higher levels in clams exposed to CBZ and pH, especially when combined. The activities of SOD and CAT were maintained or significantly decreased in comparison with the control, respectively, justifying higher LPO levels observed after exposure to CBZ, pH 7.1 and their combination. In conclusion, *S. plana* avoided oxidative damage under low pH for a long period (28 days), showing higher survival when exposed to this stressor compared to CBZ or CBZ combined with pH 7.1. The toxicity was higher when clams were simultaneously exposed to both stressors (CBZ + pH 7.1) since individuals' survival was reduced and oxidative stress increased when compared to single exposures.

198

Coping with pharmaceuticals and personal care products (PPCP) in a changing ocean: bioaccumulation and ecophysiological implications in seabass (Dicentrarchus labrax) exposed to diclofenac

A. Maulvault, IPMA, I.P. / Division of Aquaculture and Seafood Upgrading; E.A. Sampaio, IPMA, I.P.; S. Cunha, ICETA; V. Barbosa, R. Alves, P. Pousão, IPMA / Division of Aquaculture and Seafood Upgrading; M. Diniz, Nova University of Lisbon / Centre of Fine Chemistry and Biotechnology; R. Rosa, CIIMAR; A. Marques, IPMA, I.P.

Anthropogenic activities have led to great environmental challenges: remarkable chemical contamination and dramatic climate change. Both factors strongly affect marine ecosystems and are expected to worsen in the future, threatening marine species' welfare and survival. It is unknown how marine organisms will cope with the exposure to chemical contaminants under climate change. Given the lack of data and regulation for the the presence of the emerging the pharmaceutical and personal care products (PPCP), monitoring of these compounds in the aquatic environment becomes crucial. In this way, assessing climate change effects is even more imperative. Hence, the present work aimed to assess the synergistic effects between climate change and the exposure to the widely and massively used PPCP diclofenac, by analysing its bioaccumulation and elimination process in the European seabass (*Dicentrarchus labrax*), as well as the physiological and biochemical implications to this fish species. Results suggested that temperature and pH strongly influences the bioaccumulation and elimination of diclofenac, particularly it's partitioning in the different fish organs. Widespread impairments in fish enzymatic machinery, and a positive correlation between diclofenac accumulation and fish biochemical responses were observed. Hence, the deleterious synergistic effects of ocean warming and acidification combined with diclofenac exposure observed in the present work evidenced great biological challenges to marine vertebrate populations in the NE Atlantic coastal ecosystems in the future.

199
Global warming causes conflicting effects on pesticide sensitivity: integrating multiple effects across latitudes
L. Op de Beeck, Laboratory of Aquatic Ecology & Evolutionary Biology - KU Leuven / Biology; J. Verheyen, University of Leuven / Biology Laboratory for aquatich ecology evolution and conservation; R. Stoks, KULeuven / Department of Biology
Freshwater biodiversity is particularly vulnerable to global warming and pesticides. Both stressors are directly linked because most pesticides are assumed to become more toxic at high temperatures. This may, however, not reflect the net effect of pesticides in nature when their degradation is more rapidly at higher temperatures. Understanding how both stressors interact is therefore crucial to correctly estimate the ecological impact of pesticides in a warming world. Therefore, we investigated in larvae of the damselfly *Ischnura elegans* multiple effects of the pesticide chlorpyrifos (CPF) under a simulated global warming scenario on life history, thermal tolerance and physiology. By studying both low- and high-latitude populations we applied a space-for-time substitution to assess the role of thermal adaptation in shaping the vulnerability to CPF under global warming. CPF exposure negatively affected survival, growth rate, thermal tolerance, fat content and AchE activity and increased lactate dehydrogenase (LDH) activity. Under simulated warming CPF caused lower mortality, a less strong growth reduction (in high-latitude larvae) and less oxidative damage than at 20°C. This could be explained by the lower degradation of CPF at 20°C leading to a higher accumulation after four pulses compared to the treatment at 24°C. This indicates that testing effects of global warming on pesticide sensitivity may be misleading in experiments that keep pesticide concentrations artificially constant. Furthermore, this temperature effect on mortality was fine-tuned by local thermal adaptation with at a given temperature mortality being lowest in larvae tested at their local mean summer water temperature. This pattern suggests that the lower impact of a temperature increase of 4°C on the toxicity of CPF can be further strengthened if gradual thermal adaptation takes place in the high-latitude larvae. Notably, CPF exposure reduced the thermal tolerance and therefore the ability to deal with heat waves. This generates the complex scenario where exposure to CPF under a realistic field application scenario may cause lower direct negative effects under global warming, yet may cause higher negative effects in case of heat waves which are expected to increase in strength, duration and frequency under global warming.

Exposure to a heat wave under food limitation makes an agricultural insecticide lethal
L. Janssens; K. Dinh Van, KULeuven; R. Stoks, KULeuven / Department of Biology
Synergistic combinations of anthropogenic stressors are of major concern for biodiversity loss. While extreme temperatures and exposure to agricultural pesticides are becoming more frequent and intense under global change, their joint effects have been poorly studied. The potential for delayed interactions, and their modulation by the often co-occurring food limitation may be especially problematic, yet have been ignored. We tested for the effects of a transient heat wave combined with food limitation, and subsequent exposure to a widespread agricultural pesticide (chlorpyrifos) in *Coenagrion puella* damselfly larvae. The direct effects of the heat wave included a 3% increase in mortality and reductions in immune function (measured as activity of phenoloxidase, PO) and in metabolic rate (measured as activity of the electron transport system, ETS), which were not magnified by starvation. Starvation had both direct and delayed negative effects on growth rate, Hsp70 levels, total fat content, and activity levels of PO and ETS. Exposure to chlorpyrifos negatively affected all response variables, yet for mortality and immune function this was only in larvae previously exposed to the transient heat wave and starvation. This delayed synergism was especially striking for mortality: while the heat wave caused only minor mortality and starvation had no direct effect on mortality, chlorpyrifos caused considerable (48%) mortality, yet only in larvae that were previously exposed to both the heat wave and starvation. This could be partly explained by the inhibition of acetylcholinesterase (AChE) and the cumulative metabolic depression caused by each of these stressors. Furthermore, the delayed negative effects of the transient heat wave and starvation, combined with the direct negative effect of chlorpyrifos, considerably reduced larval growth rate. The here identified delayed synergism provides a novel explanation for the poorly understood potential of heat waves and of sublethal pesticide concentrations to cause mass mortality.

Multi-biomarker responses between two dreissenid species in a global change context
M. Potet, Université de Lorraine, CNRS UMR 7360; L. Giamberini, P. Rousselle, Université de Lorraine, CNRS UMR 7360 / LIEC CNRS UMR; S. Pain-Devin, Université de Lorraine - UL / LIEC CNRS UMR; S. Devin, LIEC - Université de Lorraine - CNRS / LIEC CNRS UMR
Under actual climate warming, further stressors such as contaminants might impact species distribution and ecosystems functioning. The ability of ectotherms to handle multiple stresses (*e.g.* a combination of metallic contamination and temperature change) will depend on their acclimation or adaptation capacities. Current literature raises the importance of understanding how organisms will respond and adapt to these changes in abiotic factors. Biomarkers can be used as very informative tools to evaluate exposure and effects of stressors on organisms. The freshwater bivalve *Dreissena polymorpha* is currently used in biomonitoring because it is a widespread species, tolerant to a wide range of environmental conditions and contaminants. It presents a sedentary lifestyle and is a filter feeder, often used to evaluate the accumulation of contaminants in its tissues and their subsequent effects on biological processes. However, *D. polymorpha* populations are declining because of their replacement by a sister species, the quagga mussel, *Dreissena rostriformis bugensis*. In this global change context, we wondered whether the quagga mussel might be more tolerant to environmental stressors, explaining its greater invasiveness. To evaluate the response pattern of both species, we exposed them to heat stress and metallic contamination. Mussels were placed in experimental beakers under five different treatments: control (no exposure), nickel (Ni) at 20 and 500 $\mu g\ L^{-1}$ and chromium (Cr) at 5 and 15 $\mu g\ L^{-1}$. Beakers were maintained at two temperatures: 12 °C, corresponding to the acclimation temperature, and 17 °C, to simulate a thermal stress. A battery of biomarkers, representative of both physiologic and antitoxic functions, was monitored (*e.g.* filtration activity, energetic reserves, antioxidant defences, detoxification mechanism). This multi-biomarker approach evidenced that the two species do not respond to multiple stresses the same way. We first showed that temperature do not affect biomarker responses four days after heat stress. However, we evidenced great differences between the two species, since biomarker responses were generally higher for *D. polymorpha* than for *D. bugensis*, particularly in non-exposed organisms. Even if the two species assimilated both metals the same way, the effects of contamination on biomarker responses were more marked in *D. polymorpha*, especially under nickel exposure.

Higher tier tests in the risk assessment of plant protection products (I)

202
Aquatic mesocosm studies - use in risk assessment
M. Hamer, Syngenta / Environmental Safety; E. Bruns, Bayer CropScience AG / BCS D ETX Ecotoxicology; P. Dohmen, BASF SE / Landw Versuchsstation APDRO
Mesocosm studies are a useful tool in aquatic risk risk assessment, as the highest experimentaltier in aquatic effects assessment. These studies are the only experimetal studies looking at porpulations and communities potential effects and recovery and as such aligned with the specific protection goals for aquatic invertebrates and primary producers. Furthermore they are the refence tiers against which lower tier approaches can be calibrated. Despite this, the conduct of such studies is reducing because they are becoming less accepted in regulatory risk assesment, as the interpretation of such studies and the assessments become ever more precautionary. The background to mesocosm studies and information on their design, conduct and interpretation can be found in the EFSA Aquatic Guidance. New validity criteria have recently been developed with respect to the number of sensitive and vulnerable taxa which should be present in the test systems and meet statistical criteria (appropriate minimal detectable difference – MDD) with the aim of ensuring that the effects could be detected and recovery observed. Strict adherence to these criteria can lead to studies being declared invalid and consequently ignored in the risk assessment. Despite not meeting the new criteria studies can still contain very useful information and should not be ignored in the assessment. Mesocosm studies can be bespoke to answer specific questions pose by the problem formulation and they should be evaluated similarly. Illustrated by examples, it will be shown how mesocosm studies can contribute to and inform the risk assessment, whilst potentially not fulfilling all validity criteria.

203
How to deal with multiple micro-/mesocosms studies for the ETO and ERO-RAC derivation
P. Lopez-Mancisidor, Dow Agro Sciences LLC / Ecotoxicology; N.N. Poletika, Dow Agro Sciences LLC / Field Exposure and Effects Department
In the tiered effect assessment scheme developed for the EFSA Aquatic Guidance Document (2013), in principle, all tiers are able to address the ETO (Ecological Threshold Option). However, only the model ecosystem approach (micro-/mesocosm experiments) allows to address the ERO (Ecological Recovery Option) when addressing risk to algae, vascular plants or invertebrates. In order to address the reliability of the micro-/mesocosm experiments for the ETO and ERO-RAC derivation the AGD establish some requirements to be fulfilled (e.g. at least 8 potentially sensitive populations present in sufficient number with an acceptable MDD value). In this study we selected an insecticide as a case study

for which more than 6 micro-/mesocosm studies performed in different parts of the world and/or under different experimental condition to to assess if the power of the statistical test of these studies was sufficient to demonstrate treatment-related responses. From the 6 studies evaluated 4 of them comply with the criteria (at least 8 taxa of potentially sensitive taxonomic groups with MDDabu values < 100%) proposed by Brock et al. (2015). Two studies don't fulfil the criteria proposed as there were less than 8 potentially sensitive taxonomic groups belonging to Category 1 taxa. This can be partially explained by the fact that those studies were focused only on zooplankton and the number of taxa evaluated was lower than in the other studies. The results obtained after the re-evaluation of the data are similar to those reported previously in published reviews and scientific papers and in the new EFSA Aquatic Guidance Document with an effect class 2 concentration of 0.1 μg/L. This threshold level has been derived irrespectively of climatic test conditions (temperate, Mediterranean and also tropical as is the case of Thailand) and also even irrespectively of the exposure pattern (single application simulating spray drift and repeated application simulating run-off events). This can be explained by the fact that the most sensitive taxa (crustaceans and insects) were well represented in the cosms evaluated.

204
Stream mesocosms in the context of insecticide risk assessment
L. Dören, R D; P. Janz, P. Ebke, MESOCOSM GmbH; L. Beuter, Mesocosm GmH; U. Hommen, M. Kotthoff, Fraunhofer IME; C. Schaefers, Fraunhofer Institute for Molecular Biology and Applied Ecology IME / Ecotoxicology
In the risk assessment of plant protection products (PPP) aquatic mesocosm experiments are used as higher tier tools to analyse effects in an ecosystem context under more realistic conditions than in single species tests. Therefore, mesocosm experiments should simulate realistic exposure scenarios and should feature a representative biocenosis including potentially sensitive species. Usually these experiments are conducted in lentic mesocosms (artificial ponds or enclosures) for regulatory purposes. But in certain cases lotic mesocosms (artifcial streams) may be the more appropriate choice to describe the ecotoxicological risk of a PPP in the aquatic environment. Many different factors have to be considered to decide between lentic or lotic mesocosms: The environmental behaviour of the test substance, exposition scenarios, intrinsic sensitivity of freshwater species and their vulnerability derived from their ecology. In this presentation we want to discuss these factors and bring some light in the discussion by presenting results of an experiment with four stream mesocosms in comparison with simultaneously performed pond mesocosm studies. In addition we compare the artificial stream data with the data of two local natural streams representative for a landscape with moderate agricultural use. Finally we present the results of a pilot stream mesocosm study with the insecticide carbaryl. The comparison study shows that the macroinvertebrate community of the stream mesocosms corresponds well with the reference streams regarding diversity, feeding types, ecological traits and number and abundance of taxa, which are potentially sensitive and vulnerable. Abundance and number of taxa with a high intrinsic sensitivity against carbamates, organophosphates and neonicotinoids was higher in the artificial streams than in the pond mesocosms. On the other hand, for pyrethroids the lentic mesocosms seem to be more meaningful caused by the occurrence of the focal species *Chaoborus*. First results of the carbaryl study shows, that the most sensitive macroinvertebrate taxa are Plecoptera, Gammarids, the mayfly *Ephemera danica* and the caddisfly *Polycentropus flavomaculatus*, all taxa prefering or restricted to lotic water bodies.

205
The Landau stream mesocosm facility
M. Wieczorek, N. Bakanov, C. Stang, D. Bilancia, D. Kötter, University of Koblenz-Landau; L. Lagadic, Bayer CropScience / Environmental Safety; E. Bruns, Bayer CropScience AG / BCS D ETX Ecotoxicology; R. Schulz, University of Koblenz-Landau
In the current tier-3 risk assessment for plant protection products (PPPs) in edge-of-filed surface waters risks are mainly based on pond-like mesocosm approaches. However, transient and dynamic PPP exposure scenarios as observed in lotic systems are hardly achievable in pond-like mesocosm approaches. The present compilation of studies performed at the Landau stream mesocosm facility provides knowledge on dynamic PPP exposure scenarios at different time scales (i.e. peak-, hour- and day-scale) under flow-through and recirculating conditions. To address the effects of a pesticides on aquatic plants under a day-scale exposure, the submerged macrophyte species *Elodea canadensis* and *Myriophyllum spicatum* were exposed to a sulfonylurea herbicide for 24 hours (in recirculating flow mode) followed by a subsequent PPP-free flushing period to enable a recovery period of 42 days. Two macrophyte species revealed pronounced adverse short-term effects on shoot growth and yield, but also a subsequent recovery at the end of the experiment. Preliminary to the effect assessment of insecticides on hour- or day-scale the setup of stream mesocosms with macrophytes and aquatic organisms was considered in general. Abundance and robustness of invertebrates was evaluated including sensitive and/or vulnerable species. Non-dosed streams were used to evaluate the influence of different aquatic macrophyte species and the duration of the pre-experimental period on the establishment success of macroinvertebrates. To address the stream-internal longitudinal changes of the concentrations and the residence time of PPPs a location-dependent invertebrate sampling scheme was used within the scope of a 6-hour application of the insecticide etofenprox (0.05, 0.5 and 5 μg/l; n=4). Short-term effects were observed on population and on community level. The sublethal endpoint drift was revealed as most sensitive as significant effects were visible occasionally at 0.05 μg/L for Simuliidae and at 0.5 μg/L for potentially sensitive species as Polycentropodidae. An integrated stream mesocosms test design capable of identifying inter-ecosystem boundary effects was established using the widely distributed web-building spider *Tetragnatha extensa* as a representative riparian species. On different scales of complexity, this approach may be used to evaluate PPP transfer due to emerging insects, bioaccumulation of PPPs in riparian spiders and alteration of trophic structures in riparian ecosystems.

206
Effects of chronic exposure to thiamethoxam on a summer generation mayfly population in an outdoor mesocosm
M.C. Finnegan, Syngenta; D. Pickford, Syngenta / Institute for the Environment; P. Stegger, Institut für Gewässerschutz Mesocosm GmbH; L. Dören, R D; W. Böhmer, Fraunhofer Institute IME; U. Hommen, Fraunhofer IME
The effect of neonicotinoids on mayfly nymphs has been investigated in recent literature, demonstrating they are amongst the most sensitive aquatic insect taxa to these insecticides. A publication by van den Brink et al (2015) reported the chronic effects of a continuous thiamethoxam exposure (28d) under laboratory conditions on over-wintering generation mayfly larvae (*Cloeon dipterum*); 28d EC_{10} = 0.43 ug a.s./L. A GLP outdoor mesocosm study was performed to investigate chronic effects of a continuous exposure to thiamethoxam on a summer generation mayfly (*Cloeon dipterum*) population. Twenty stainless steel enclosures within one large pond enclosure were used for the study; five untreated controls and five treatment levels with three replicates each. The treatment levels were, 0.1, 0.3, 1.0, 3.0, 10 µg a.s./L. Concentrations of thiamethoxam were maintained with twice-weekly applications to the water column via mixing. The time weighted average concentrations ranged from 93 to 108% of nominal, with a mean of 101% of nominal. Mayfly abundance was assessed with sweep-netting and substrate sampling (two baskets with aquatic macrophytes and stones). Adult emergence was also sampled. Mayfly sampling occurred weekly for the duration of the study. The % minimum detectable difference (MDD) values for larval abundance ranged from 37 to 49% up until day 27 of the study, indicating that small effects could be detected. On day 34, the MDD value was 87%, due to the natural population decline. The no-observed-effect-concentration (NOEC) for larval abundance was determined to be 0.3 μg a.s./L and the lowest-observed-effect-concentration (LOEC) was determined to be 1.0 μg a.s./L.The results for adult emergence support the observed effects on the larval population. The results of the study indicate that under conditions of continuous exposure, there is no apparent difference in sensitivity to thiamethoxam between summer generation mayfly larvae tested under field conditions and over-wintering generation mayfly larvae that were tested under laboratory conditions. This study adds to the growing debate on the effects of neonicotinoids on sensitive aquatic insects by determining a no effect level for mayfly populations in outdoor mesocosms continuously exposed to thiamethoxam, representing worst-case conditions with respect to FOCUS modelling drainage scenarios.

207
Experiences from a suite of higher-tier laboratory tests on aquatic larvae of four potentially-sensitive insects, and an amphipod, with the aim of comparing sensitivity to an insecticide
S. Priestly, F. Pickering, Cambridge Environmental Assessments; M. Allen, Cambridge Environmental Assessments CEA; S. Taylor, Cambridge Environmental Assessments; W.R. Jenkins, W R Jenkins / Regulatory Affairs Ecotoxicology
The EFSA Guidance document on tiered risk assessment for plant protection products for aquatic organisms in edge-of-field surface waters (2013) makes recommendations for assessing the risks to sensitive and vulnerable invertebrate taxa. Questions about such taxa can arise when the results from a static microcosm study are interpreted in a wider context. This is especially the case for taxa which are not represented within the microcosms, such as stonefly larvae which are found in *flowing* waters. Published comparative-assessments have suggested that invertebrates such as stonefly larvae (Plecoptera), commonly used as indicator species for water quality, are particularly sensitive to insecticides. Therefore, actually testing their *relative sensitivity* compared with taxa which are found in microcosm studies, could minimise uncertainty (and therefore the 'uncertainty factor') when implementing microcosm results in the risk assessment. A set of laboratory tests on an insecticide was undertaken by Cambridge Environmental Assessments (CEA) to assess relative sensitivity of larvae of Plecoptera (stonefly), Megaloptera (alderfly) Trichoptera (caddisfly), and to 'benchmark' this against tests on *Chaoborus* and *Crangonyx* – both of the latter two being present and sensitive to this insecticide in previous microcosm experiments. To achieve this, a novel laboratory test design using microcosm water and sediment was developed. Plecoptera and Megaloptera were collected from rivers in Southern England and Trichoptera, *Chaoborus* and *Crangonyx* were sourced from CEA microcosms.

Separate tests were conducted for each taxon using 3-litre beakers containing sediment, microcosm water, alder leaves as a source of detritus, with gentle aeration, and pebbles to simulate the natural environment of stonefly larvae. After addition of the insecticide, observations were made during 96 hours, and final counts of survival were recorded. The results were used to determine the relative sensitivity. Practical experiences will be shared on selecting test organisms based on life history and abundance, and conducting and assessing the sensitivity of these non-standard species in laboratory.

Development, standardization and implementation of LCA and integration with economics for transportation infrastructure and operations

A multi-objective optimization-based pavement management decision-support system for enhancing pavement sustainability

J. Santos; A. Ferreira, University of Coimbra / Department of Civil Engineering; G. Flintsch, Virginia Polytechnic Institute and State University / Department of Civil and Environmental Engineering

In a society where the public awareness of environmental protection is increasing remarkably and the availability of resources and funding is limited, it is more vital than ever that departments of transportation (DOTs) and decision-makers (DMs) seek new tools that enable them to make the best and most rational use of these resources, taking into account environmental and social factors, along with economic and technical considerations. However, the practice adopted by highway agencies with regards to pavement management, has mostly consisted of employing life cycle costs analysis (LCCA) systems to evaluate the overall long-term economic efficiency of competing pavement design and maintenance and rehabilitation (M&R) activities alternatives. This way of supporting the decision-making process as it relates to pavement management, in which little or no importance is given to environmental considerations, does not seem to be effective in advancing sustainability in pavement systems. In view of this, it is clear there is an urgent need for pavement management decision-support systems (DSS), which, by integrating multi-disciplinary and complementary pavement life cycle modelling approaches, enable the DMs to properly account for, consider and assess the cumulative and long-term impacts of their decisions and practices regarding sustainability goals and targets. This only can be achieved by employing techniques and tools provided with a comprehensive and wide-scoped cradle-to-grave capacity of analysis. To address this multifaceted problem, this paper presents a comprehensive and modular multi-objective optimization (MOO)-based pavement management DSS which comprises three main components: (1) a MOO module; (2) a comprehensive and integrated pavement life cycle costs - life cycle assessment (LCC-LCA) module that covers the whole life cycle of the pavement; and (3) a decision-support module. The potential of the proposed DSS is illustrated with a case study consisting of determining the optimal M&R strategy for an one-way flexible pavement section of a typical Interstate highway in Virginia, USA, which yields the best tradeoff between the following three, often conflicting, objectives: (1) minimization of the present value (PV) of the total life cycle highway agency costs (LCHAC); (2) minimization of the PV of the life cycle road user costs (LCRUC); and (3) minimization of the life cycle greenhouse gas emissions.

Aggregation Errors in Life-Cycle Assessment of Freight Trucks

M.N. Taptich, University of California, Berkeley / Department of Civil and Environmental Engineering; A. Horvath, University of California, Berkeley

Life-cycle emission factors for heavy-duty trucks found in the literature and life-cycle assessment (LCA) databases typically reflect a generic or industry-average perspective in global or regional context. As a result, emission factors often lack the specificity to accurately characterize the performance of the vehicles, which could lead to misdirected strategies and actions. We believe that by collapsing over many individual vehicles to establish a formal emission factor, this aggregation process restricts the explanatory power of LCA for individual cases by removing within-group information that may be useful for policy-making. This information includes knowledge of specific trip attributes (location, road type, time of day, etc.), vehicle attributes (gross weight vehicle rating and payload), driving conditions (levels of congestion), and characteristics of their respective supporting infrastructure systems (location of critical infrastructure and route topology). We assess the accuracy of greenhouse gas (GHG) emission factors of heavy-duty trucks by accounting for how they are utilized in real life and the sensitivity of GHG emission factors to vehicle loading factors (payloads) and commodity types transported. Case studies suggest that emission factors based on average payload always underestimate emissions. We provide examples of how existing emissions inventories change in response to infrastructure, vehicle, and payload characteristics. This research advances the scientific community's understanding of how GHG emissions from heavy-duty trucks can be allocated on more resolved spatial and temporal scales, thereby improving decision-making on a case-by-case basis.

Prospective Fleet LCA of Swiss Air Transport

B. Cox, Laboratory for Energy Systems Analysis; C. Mutel, W. Jemiolo, Paul Scherrer Institute / Laboratory for Energy Systems Analysis

This work presents a Life Cycle Assessment (LCA) of passenger aircraft travel at both the individual aircraft and Swiss fleet level with projections until 2050. In the first stage of this work we perform LCA of three different classes of aircraft with construction years ranging from 1970 to 2050. Parameters such as aircraft material composition, weight, lifetime distance travelled, fuel consumption, operating emissions, and seat load factor are modelled as variables dependant on the size of the plane, construction year, and flight distance. Future fuel consumption and operating emissions are modelled for two scenarios reflecting either a continuation of historic improvements (BAU), or an optimistic acceleration of technology improvements (OPT). Future Swiss air transport demand is modelled to increase significantly at 2.75% per year. Flight length distributions, Fleet composition, and aircraft use parameters are based on Swiss and European statistical data. Results are presented for ReCiPe midpoint for indicators: climate change, terrestrial acidification, photochemical oxidant formation, and particulate matter formation. Results show that environmental impacts are strongly related to fuel consumption. For climate change and acidification this is due to combustion in the cruise phase, while the fuel production phase is most important for other indicators, though impacts from landing and take-off cycles were also significant. Results for all impact categories varied by more than 50% depending on aircraft size and construction year. Flight distance is found to have a strong impact on per passenger kilometer (pkm) environmental impacts for flights below 1000 km, which make up approximately 20% of all pkm. Fleet average environmental impacts per pkm have decreased by over 40% since 1990, and are found to decrease by another 40 to 60% by 2050 for BAU and OPT technology development scenarios, respectively. The total pkm performance of the fleet is forecast to increase by over 2.5 times by 2050 compared to 2015. These large increases in future demand are expected to leave Swiss fleet level environmental impacts at levels similar to today's, even with greatly accelerated technology development. Thus, reductions in fleet impacts from Swiss passenger air travel are only likely in the future with growth rates much slower than those currently predicted. This work was completed within the SCCER Mobility (www.sccer-mobility.ch).

Using life-cycle assessment to guide the development of bio-based fuels, lubricants, rubber, and plastics

C.D. Scown, Lawrence Berkeley National Laboratory / Energy Analysis Environmental Impacts

Decarbonizing the transportation sector is critical to achieving global climate change mitigation. Although biofuels will play an important role in conventional gasoline and diesel applications, reducing societal reliance on oil and gas cannot be eliminated unless the full suite of products can be replaced. In this study, we explore the climate implications of producing bio-based fuels, lubricants, and precursors for rubber and plastics. We show that, guided by life cycle assessment combined with linear programming, integrated sugarcane biorefineries for producing jet fuels and lubricants could be built to minimize the overall GHG impact or maximize total energy output through novel combinations of furan and fermentation pathways.

Using LCA for Comprehensive Sustainability Assessments of Road Pavements

S. Brodie, University of Notthingham / Civil Engineering; J. Bryce, AMEC Foster Wheeler; D. Lo Presti, The University of Nottingham / Nottingham Transportation Engineering Centre NTEC; E. Parry, US Environmental Protection Agency / National Homeland Security Research Center

A review of sustainability assessment tools for transportation systems shows that sustainability is often evaluated based on the goal of improving the environmental state (Brodie et al. 2013); however, comprehensive sustainability must also account for improvements to the social and economic state of society. In pavement rating tools applied at the project level, such as BE^{2}ST-in-Highways and GreenPave, environmental impacts are evaluated using LCA, but tools are needed in addition to LCA to support decision making for comprehensive sustainable outcomes. The LCA methodology has been expanded to apply to economic aspects through LCCA and attempts have been made to measure social aspects similarly (SLCA). This paper reviews several LCA methods as environmental calculators for use in sustainability assessments of road pavements and explores LCCA and SLCA methodologies. The results highlight the uses and limitations of LCA, LCCA, and SLCA for comprehensive sustainability evaluation and provide insight into approaches to address limitations and to improve sustainable decision making at the project level.

Biological effects of emerging micro pollutants at realistic environmental concentrations (II)

213
Effect of environmentally realistic doses of pesticides on tritrophic interactions in grass strips
C. Le Lann, UMR CNRS 6553 Ecobio / UMR CNRS ECOBIO; J. Queffelec, C. Sulmon, University of Rennes 1 / UMR CNRS ECOBIO
In agricultural areas, grass strips implemented as buffer zones to protect water quality are regularly subjected to residual pesticide contaminations mainly resulting from runoff. Grass strips are also reservoirs of biodiversity for plants and insects that are thus potentially exposed to these compounds. Within plant-insect trophic chains, interactions between trophic levels are governed by exchanges of resources (nutrients, water) as well as chemical signals. As a consequence, each trophic level can regulate lower (top-down control) and higher (bottom-up control) trophic levels. This work aimed at studying the effects of environmentally realistic low doses of pesticides on the interactions between *Lolium perenne* (ryegrass), an aphid pest *Rhopalosiphum padi* and its parasitoid *Ephedrus plagiator*. To simulate a runoff-resulting pesticide exposure of the trophic chain in a context of grass strip, the plants were exposed *via* their root system to an herbicide (isoproturon) and an insecticide (Thiamethoxam), applied alone or in combination. Insect exposure was thus related to pesticide transfer along the trophic chain. We found that the three trophic levels were affected by pesticides, the combination of both compounds resulting in synergistic, additive or antagonistic effects depending on pesticide dose and traits measured. Moreover the observed effects were found not to be always linked to deterioration in the quality and / or quantity of resources produced by lower trophic levels, suggesting actions of pesticides on non-target organisms as chemical stressors and/or potentially alteration of plant-insect chemical signals. However, pesticides effects can be offset between biological organization levels. Thus, in agricultural landscapes, the interactions between plants, herbivores and their natural enemies are subject to change with pesticide exposure, even at low doses typically found in grass strips.

214
Signalling and regulation pathways involved in cryptic effects induced by residual levels of pesticide degradation products on higher plants
D. ALBERTO, Université de Rennes 1 / UMR CNRS ECOBIO; A. Serra, I. Couee, C. Sulmon, Université de Rennes / UMR CNRS ECOBIO; S. Pateyron, Université dEvry Val dEssonne / URGV INRA Transcriptomic platform; D. Renault, Université de Rennes / UMR CNRS ECOBIO; G. Gouesbet, UMR CNRS ECOBIO
Pesticides are pollutants of high concern due to environmental ubiquity resulting from extensive use in modern agriculture and persistence in soil and water. Study of plant behaviour toward such molecules and their breakdown products in situation of residual pollution is important to evaluate toxicity at low concentration in the context of environmental risk assessment. Studies at various spatial scales have highlighted frequent occurrences of major herbicide breakdown products in surface and ground water. In order to understand mechanisms underlying the impact of such molecules, the model plant *Arabidopsis thaliana* was confronted with low levels of breakdown products of widely used herbicides (aminomethylphosphonic acid for glyphosate, desethylatrazine and hydroxyatrazine for atrazine), quantified in soils of field margins in an agriculturally-intensive area. Integrative analysis of physiological, biochemical and molecular responses showed that these residual xenobiotics rapidly led to cryptic effects with major reorientations of carbon and nitrogen metabolism and gene expression changes. The extent of such changes, in absence of significant action on primary targets, was consistent with involvement of early regulatory processes and signalling mechanisms. In order to identify such xenobiotic-related signalling, *Arabidopsis* seedlings were subjected to low levels of structurally-related xenobiotics (atrazine, hydroxyatrazine, desethylatrazine) under conditions of No Observable Adverse Effects, and a genome-wide transcriptomic analysis (CATMAv7 microarray) was carried out. Functional analysis of differentially expressed genes and of their promoters revealed that signalling pathways related to plant hormones (cytokinins, ABA), low energy sensing (MYB2), environmental stresses (light, drought, heat, oxidative stress, hypoxia) and biotic interactions (WRKY40) were involved in xenobiotic signal transduction. Further studies will use hormone analogues and inhibitors, or mutants related to hormone signalling, in order to analyse xenobiotic-hormone interactions. Characterisation of xenobiotic signal transduction pathways should be of interest for herbicide management in crop systems and for protection of wild plant communities and ecosystem functioning. Identification of crosstalk processes between xenobiotic, abiotic and biotic stress signalling may give novel insights into the interplay between chemical pollution and climate change stressors.

215
The effect of marine litter at cell level: cytotoxicity evaluation of common nanomaterials and emerging contaminants
G. Schirinzi; J. Sanchís, IDAEA-CSIC / Water and Soil Quality Research Group; N. Perez, CSICIQAC; C. Rossini, Thermo Fisher Scientific; M. Farre, IDAEA-CSIC; D. Barcelo, IIQAB-CSIC / Dept Environmental Chemistry
During the past decade, new technologies were based on the use of efficient and cheap alternative materials, according to industrial interest. Therefore, a lot of common commercial products are currently made of nanomaterials or synthetic materials, such as plastic. Their input to the environment, years after years, contributes to increase the number of waste in coastal waters, estuaries and oceans. This is also known as marine litter. Therefore, the aim of recent several researches is to study the toxic effects of these compounds, the environmental deterioration and human health effects caused by them. The scope of this study was to understand the toxicity of common NMs and emerging contaminants at cell level in terms of oxidative stress and cell viability and to compare the cytotoxic response of two different cell lines exposed to the same conditions. In addition, with regards to carbon based nanomaterials, such as fullerenes (C_{60},C_{70},..), due to their sorptive properties, they may act as carriers for other contaminants, providing rapid and long-range transport or immobilizing them. The change in the bioavailability of other contaminants is known as Trojan Horse Effect. In the present work, the cytotoxicity of nanomaterials (including fullerene soot, graphene nanoflakes, and several other of metal and metal oxide nanoparticles) has been evaluated in vitro using two different cellular lines: T98g, cerebral human cells, and HeLa. The cells were exposed during 24-48 h to different level of contaminants from 10 ng/ml to 60 μg/ml. Furthermore, cells were also exposed to increasing concentration of different binary mixtures containing fullerene soot, in order to evaluate Trojan Horse Effect. The cell viability and cell's oxidative stress were measured via High Content Analysis. Cells were selected as objects in two channels with two different wavelength (λ_1=485 nm and λ_2=549 nm) close to the Hoechst and DHE emission maximum, respectively. The obtained results contribute to the current knowledge of the cytotoxicity of both nanomaterials and microplastics. According to them, oxidative stress is one of the mechanisms that explain the toxicity of these emerging contaminants at cell level, as has been observed for both cell lines. In addition, carbon nanomaterials have the potential to interact in a complex way with the co-occurring contaminants, changing the bioavailability and, therefore, their resulting toxicity in either a synergistic or an antagonistic manner.

216
Seabream macrophages responses to combined stressors: gene expression changes
N.G. Ferreira, University of Porto / CIIMAR; . Barreto, University of Aveiro / Department of Bioloy CESAM; T. Trindade, University of Aveiro / Department of Chemistry CICECO; M. Teles, Universitat AutÃnoma de Barcelona / Department of Cell Biology Physiology and Immunology; L. Tort, Universitat Autonoma Barcelona / Department of Cell Biology Physiology and Immunology; A.M. Soares, Universidade de Aveiro / Department of Biology and CESAM; L. Guimaraes, CIIMAR University of Porto / METOX Coastal and Marine Environmental Toxicology; M. Oliveira, University of Aveiro
Nanoparticles (NPs) and pharmaceuticals are among the different classes of contaminants of emerging concern (Buchberger 2007, Sauve and Desrosiers 2014). NPs are increasingly used in several areas of human activity, despite the lack of knowledge regarding their impact in ecosystems. Pharmaceuticals have a bioactive nature and their consumption is increasing worldwide. Further, their removal by wastewater treatments is not sufficiently efficient, and in some cases more toxic or slowly degradable transformation products are formed (Oliveira et al. 2014). This concern may be emphasized taking into account that, in the environment, such contaminants may occur simultaneously and their interaction may become more harmful. Few studies have focused on the combined effects of these contaminants on coastal and estuarine ecosystems. This study aimed to test the *in vitro* effects of gold nanoparticles (AuNPs), with different coatings, and the human pharmaceutical gemfibrozil (GEM) in gilthead seabream (*Sparus aurata*) macrophages. Macrophage gene expression after exposure to these contaminants (individual or combined exposures, and combined with bacterial lipopolysaccharide, LPS) was assessed focusing on different pathways (e.g. apoptosis, inflammatory responses, antibacterial responses, oxidative stress or calcium signalling). The present study revealed different patterns of response to AuNPs with different coatings. Citrate coated AuNPs induced expression of genes such as lysozyme, interleukin-1P (IL1P) or NAPH oxidase (NCF4). Polyvinylpyrrolidone coated AuNPs elicited downregulation patterns of genes such as caspase 1 (CASP1), tumour necrosis factor P (TNFA) or extracellular calcium sensing receptor precursor (GPCR). It is also noteworthy that, with the exception of IL1ю, all the other genes showed downregulation for the ternary mixture treatment AuNPs+LPS+GEM. In the combined exposure of AuNPs+GEM, genes related to similar pathways (CASP1 / TNFA or NCF4 / GPx4b) presented opposite patterns of expression. Gilthead seabream macrophages showed to be a useful in vitro model to investigate combined effects of these emerging contaminants.

Biological-based profiling of wastewaters from sources to the discharge into the environment
a. guillon, Suez / CIRSEE; N. Creusot, INERIS; J. Couteau, TOXEM; N. Dumoutier, CIRSEE Suez Environnement; M. Esperanza, Suez Environnement; S. Martin-Ruel, CIRSEE Suez Environnement; M. Dévier, LPTC-EPOC, University of Bordeaux / Oceanic and Continental Environments and Paleoenvironments; H.

Budzinski, University of Bordeaux / UMR EPOC LPTC; S. Ait-Aissa, INERIS / Ecotoxicology Unit; Y. Penru, Suez Environnement SAS
Aquatic ecosystems are widely contaminated by trace micropollutants that may represent a risk for human health and wildlife. Even if some compounds are well removed by wastewater treatments, the discharge of effluents remains one of the main entry of several micropollutants in the environment. It is particularly worrying for the compounds that are endocrine disruptors and/or that can induce genotoxicity. New approach using quantitative biological activities has to be applied along the water line, especially to monitor the pollution of wastewater. The objective of this study was to apply a panel of *in vitro* bioassays to determine water contamination profiles from the wastewater network to the outlet of the WWTP. A panel of bioassays were applied on various samples collected in six sites on the network, along the WWTP in order to evaluate the impact of biological treatment and tertiary ozonation. Selected i*n vitro* bioassays, applied on water SPE extract, enabled detection of active chemicals responsible of endocrine disruption (estrogen, androgen, progestogen, mineralocorticoid, glucocorticoid, pregnane X and dioxin receptors) and the genotoxicity was evaluated by using the SOS Chromotest. In all sites along the wastewater network, ER, AR, MR activities and genotoxicity were detected. GR activity was measured at only three points of the network and was particularly important in the WWTP influent. Endocrine disruptor activities as well as genotoxicity were detected in raw wastewater (WWTP influent). Biological treatment highly reduced ED activities and genotoxicity. Nevertheless residual activities were still detected in the tertiary effluent. Results of the 1st sampling campaign allowed the identification of three notable points of interest on the network and at the WWTP influent. Results of two next sampling campaigns will help to confirm these “hot-spot” sites in order to apply effect-directed analysis to perform chemical identification of the compounds responsible of endocrine disruption activities and/or genotoxicity.

Effects of magnetic microparticles used for phosphorus removal in eutrophic waters on plankton community
A. Del Arco, M.. Salcedo, University of Granada / Ecology; A. FUNES, University of Granada; I. De Vicente Ãlvarez-Manzaneda, University of Granada / Ecology
Eutrophication is a worldwide concern causing environmental degradation and compromising water resources use. Magnetic particles have been recently proposed as a promising method to adsorb and remove phosphate from lake water and sediment. However, before this method is applied into the whole-lake experiment, ecotoxicological studies must be perform to assess the effect of such microparticles on the aquatic community. In previous studies, EC50 for standard specie as D. magna and Chironomus sp. has been assessed, here we present a microcosms study to further explore the effects of these particles on the whole community. Our specific hypotheses were: a) the addition of MPs will cause transient effect on the structure of plankton community allowing its recovery by the end of the experiment and b) a top-MPs spike will prone more changes on plankton community than a bottom addition because of a longer exposition time.In order to test these hypotheses, a microcosms experiment with three different treatments of MPs (i.e., control, bottom_addition and top_addition) was set-up. Bottom addition simulates an addition of the particles directly into the sediment; and, top addition if it would be spiked at the surface of the water column. The amount of amended MPs was the same for bottom and top addition treatments and it was based on the calculations of how much MPs are necessary for trapping all sediment mobile P pool (P_{Mobile}). However, and based on previous studies, we decided to add the double of that value in order to counteract chemical interferences. This experiment has two goals: first, to assess the effects of magnetic particles on the plankton community; and, second, to estimate the efficiency of phosphorus removal by the mpFe.The experiment was performed in outdoor microcosms (40 L volume) consisting of a stabilization period of 10 days, particles addition and retrieval after 24 hours simulating real field application, 79-days assessment under aerobic conditions and 5-days (stating on day 80) under anoxic conditions. Plankton abundance, species composition and richness are to be determined. Neither ChlB*a*_or oxygen concentration denoted statistical differences along the experiment between control and treatments. It may mean no changes of phytoplankton abundance or zooplankton grazing pressure but may hide community structural and richness changes. Based on chemical analysis, phosphorus was successfully removed by the MPs added with no detectable effect on the current biological parameter assessed.

Ecotoxicology and risk assessment of nanomaterials - Interactions at nano-bio interface (III)

Effects of engineered nanoparticle-contaminant mixture exposures to aquatic organisms
J. Farkas, SINTEF Materials and Chemistry; A. Booth, SINTEF Materials and Chemistry / Environmental Technology; I. Salaberria, NTNU University / Biology; T. Ciesielski, Norwegian University of Science and Technology / Dept of Biology; B. Glomstad, F. Zindler, Norwegian University of Science and Technology; D. Altin, BioTrix; A. Olsen, Norwegian University of Science and Technology; W. Posch, Medical University of Innsbruck; B. Styrishave, University of Copenhagen / Section of Analytical Biosciences Department of Pharmacy; B. Jenssen, Norwegian University of Science and Technology / Biology
Due to their high surface reactivity engineered nanomaterials (ENMs) can interact with other anthropogenic contaminants, potentially influencing their environmental distribution, bioavailability and toxicity. Suggested mechanisms behind those altered toxic effects include changes of contaminant bioavailability caused by contaminant adsorption to ENMs, or an altered toxicity due to interactive toxic effects of mixture exposures. Here we want to summarise results from a range of experiments investigating the effects of several ENM-contaminant mixtures: carbon nanotubes (CNTs)-phenanthrene; titanium nanoparticles (TiO_2NP)-benzo(a)pyrene; silver nanoparticles (AgNP)-water soluble faction of crude oil (WSF); and AgNP-17?-ethinylestradiol. Studies included different aquatic organisms, reaching from the unicellular freshwater algae *Pseudokirchneriella subkapitata* to the marine flatfish *Scophthalmus maximus*. The ENMs were characterised and their behaviour in the tested environmental matrices was determined. ENM-contaminant interactions, their uptake in organisms and effects on contaminant bioavailability were investigated. To determine potential changes in toxic effects, suitable endpoints or biomarkers were analysed for each test species. All tested nanomaterials were found to be taken up or to be associated to organisms' surfaces; however interaction between ENM and contaminants and effects on bioavailability and toxicity varied. Adsorption of hydrophobic PAHs was observed to CNT and TiO_2NP. Undergoing aggregation, both CNTs and TiO_2NPs reduced dissolved PAH concentrations. However, both dissolved and ENM-associated appeared to remain bioavailable to varying extends. Similarly, both, single and mixture exposures of AgNP and the WSF of North Sea crude oil, caused activation of oxidative stress related biomarkers in calanoid copepods. The presence of AgNP did not significantly change 17?-ethynylestradiol bioavailability to juvenile turbot. Impacts on steroid hormone concentrations in mixed exposures followed 17?-ethynylestradiol single contaminant effects, however, impacts on some hormones were slightly increased in mixed exposures. ENM-contaminant mixture effects do not follow a general mechanism. Their interaction and mixture toxicity depends on multiple factors, including ENM material and contaminant properties. Further research is needed in order to provide sound data for ENM environmental risk assessment, which needs to include risks from ENM-contaminant mixtures.

220
Long term toxicity of Ag-NM on soil nitrifying bacteria after biotransformation in WWTPs
M. Kraas, Fraunhofer IME - Institute for Molecular Biology and Applied Ecology / Ecotoxicology; R. Kaegi; K. Schlich, Fraunhofer IME - Institute for Molecular Biology and Applied Ecology; K. Terytze, Freie Universität Berlin / Earth Science; K. Hund-Rinke, Fraunhofer IME
Silver nanomaterials (Ag-NMs) are used in many cosmetics and textiles because of their antimicrobial properties. Several studies have shown that silver is released from textiles during washing and reach wastewater treatment plants (WWTPs), where significant amounts adsorb to sewage sludge. As sewage sludge is used as fertilizer in agriculture, adsorbed NMs enter the soil resulting in a negative impact on soil microorganisms. The aim of our study was to investigate the influence of sulfidation as one of the observed transformation processes occurring in WWTPs on the bioavailability of Ag-NMs. Ag_2S is less toxic than Ag^+, therefore, a comprehensive risk assessment regarding the pathway “influent – WWTP – soil” requires information on the effect of sulfate in wastewater on the bioavailability of Ag-NMs. For that reason we first simulated the transformation processes in laboratory WWTPs. In a second step the processes during sludge conditioning were simulated using two different methods. The sludges were split into half, one half was directly applied into soil the other half anaerobically digested before mixing the biosolids into soil. To investigate potential effects on soil microorganisms the ammonium oxidation test (ISO 15685) was performed at regular intervals. Sewage sludge and soil samples were investigated with TEM EDX. In the simulation of WWTPs no negative impact on the microbial activity was observable. The soil ammonium oxidysing bacteria in the directly applied treatments were more than 50 % inhibited, the anaerobically digested ones nearly complete. The different sulfate levels had no influence on the bioavaiability of Ag-NM. The TEM EDX analysis also showed no differnce between the to sulfate treatments. After processing The particles EDX spectra in the sewage sludge indicated Ag_2S by a perfect matching 2:1 ratio and the particle size was those of the pristine material NM-300K. The EDX spectra after long term incubation in soil samples indicated Ag_2S as well, but we also found different Ag-species. Although we found mostly Ag_2S in sewage sludge and soil the long term study with ammonium oxidising bacteria resulted in strong inhibition in all treatments. Therefore it can not be concluded that the treatment of wastewater and sewage sludge inevitably results in nontoxic Ag-transformation products.

221
Toxicity of TiO2 nanoparticles on soil nitrification at environmentally relevant concentrations: Evidences for an absence of classical dose-response

relationships

M. Simonin, University Claude Bernard Lyon 1 / Microbial Ecology Lab; J.M. Martins, CNRS / LTHE lab; A. Calas, University Joseph Fourier Grenoble 1 / LTHE lab; G. Uzu, IRD / LTHE lab; A. Richaume-Jolion, University Claude Bernard Lyon 1

Nitrification is a crucial microbiological process for soil fertility depending on the combined activity of ammonia- and nitrite-oxidizers. This key step of the nitrogen cycle is known to be very sensitive to environmental stressors. However, the impact of emerging pollutants such as titanium-dioxide nanoparticles (TiO_2-NPs) which are increasingly released in agricultural soils, remains to be investigated, especially at very low concentrations (< 1 mg kg^{-1} dry soil) (Sun et al. 2014; Simonin & Richaume 2015). We assessed the impact of eight TiO_2-NPs concentrations ranged from 0.05 up to 500 mg kg^{-1} dry soil in soil microcosms on nitrification activity and abundance of ammonia-oxidizing archaea (AOA), bacteria (AOB) and nitrite-oxidizers (*Nitrobacter* and *Nitrospira*) using quantitative PCR. In addition, aggregation and oxidative potential of TiO_2-NPs were measured in soil solution to identify the main drivers of TiO_2-NPs toxicity in soil. After 90 days of exposure, AOA appeared to be the most affected by TiO_2-NPs, while *Nitrospira* seemed insensitive to this contamination. AOB and *Nitrobacter* abundance exhibited similar responses. The activity was reduced by the lowest (0.05 mg kg^{-1}) and the highest (100 and 500 mg kg^{-1}) TiO_2-NPs concentrations. Interestingly, all indicators exhibited a non classical dose-response relationship that did not enable to calculate effect concentrations. This results could be linked to the influence of NPs concentration on the aggregation and oxidative potential of TiO_2-NPs assessed in soil solution. In fact, TiO_2-NPs aggregation was increased with concentration, while oxidative potential was consequently decreased. Thereby, TiO_2-NPs exhibited the largest toxic potential in soil solution at the lowest concentrations that may explain the negative effects found at very low concentration (< 1 mg kg^{-1}) on nitrification activity and nitrifiers abundances. Altogether these results pointed out the need to include very low concentrations of NPs in soil risk assessment studies. This study also emphasized that classical approaches for risk assessment based on dose-response toxicological tests are not pertinent for NPs in soil and highlights the necessity to characterize NPs properties for each concentration used in conditions close to those encountered in soil.

222

There are more than species differences: challenging the immune system with nanoparticle's sex-specific biological identity

Y. Hayashi, Aarhus University / Department of Molecular Biology and Genetics; T. Miclaus, Aarhus University / iNANO Interdisciplinary Nanoscience Center; S. Murugadoss, M. Takamiya, KIT Karlsruhe Institute of Technology / ITG Institute of Toxicology and Genetics; C. Scavenius, K. Kjær-Sørensen, J.J. Enghild, Aarhus University / Department of Molecular Biology and Genetics; U. Strähle, KIT Karlsruhe Institute of Technology / ITG Institute of Toxicology and Genetics; C. Oxvig, Aarhus University / Department of Molecular Biology and Genetics; C. Weiss, KIT Karlsruhe Institute of Technology / ITG Institute of Toxicology and Genetics; D.S. Sutherland, Aarhus University / iNANO Interdisciplinary Nanoscience Center

We have previously reported that, through formation of a protein corona, the same nanoparticles can acquire a quite different biological identity depending on the species-specificity of the proteome to which they are exposed, and that they likely differ in their fate under immune vigilance. Here we hypothesise that if the protein repertoire diversity matters in general (not simply because of significant cross-species variations), sex differences in the proteome would translate into differential corona formation even within the same species. In this study, we show for the first time that the protein repertoire differences by sex determine nanoparticle's sex-specific biological identity, and that immune cells in zebrafish interact differentially with those nanoparticles *in vitro*. For the formation of protein coronas around 70 nm silica nanoparticles, zebrafish blood plasma was collected separately from female and male adult zebrafish (*Danio rerio*) and the obtained blood plasma was referred to as DrBP-F and DrBP-M, respectively. As previously performed, we firstly characterised each type of nanoparticle-protein complexes as-is and under the exposure condition, and presumed that the main difference between the coronas formed of DrBP-F/M is the biological identity, rather than physicochemical parameters such as colloidal stability. Among the strongly-bound proteins in the corona, female-specific proteins were identified to be vitellogenin, whereas the lack of vitellogenin in the male counterpart seemed to have resulted in preferential enrichment of fetuin. We then exposed primary haematopoietic cells harvested from adult zebrafish to the nanoparticles with a pre-formed corona of DrBP-F or DrBP-M. Interestingly, it was those with a pre-formed corona of DrBP-F that resulted in a higher degree of cellular accumulation *in vitro*, particularly in the myeloid population. What we find striking is that the local build-up of single endogenous proteins at nanoparticles can dictate enhanced immune recognition; in the case of vitellogenin the nanoparticles would otherwise travel along with those proteins bearing the possibility to disturb vitellogenesis. The concept of sex differences in the corona proteome should therefore deserve further attention particularly for oviparous animals.

223

Accumulation, speciation and phytotoxicity of pristine and aged silver nanoparticles to wheat

A. Pradas, ISTerre (Institut des SCiences de la Terre-UNiversité Joseph Fourier) / Geochimie; H. Castillo-Michel, ESRF-The European Synchrotron / ID; M. Carriere, CEA / INACSCIBLAN; C. Levard, V. Vidal, CEREGE; G. Sarret, ISTerre / Geochimie

Silver nanoparticles (Ag-NPs) are used in a wide range of consumer products due to their biocidal action. However, they have been demonstrated to be very easily leached from these products leading to their inadvertent release into the environment. The application of biosolids, in which Ag-NPs leached to sewer systems are retained, as fertilizer in soils, together with the novel use of nanopesticides, makes plants to be significant biological receptors of Ag-NPs. The objective of this work was to compare the induced phytotoxicity as well as Ag distribution and speciation in wheat roots exposed to pristine and aged (sulfidized) Ag-NPs in hydroponics. $AgNO_3$ treatment was used to identify the mechanisms exclusively due to Ag+. By the combination of X-ray Fluorescence (μXRF) and micro X-ray absorption spectroscopy (μXANES), Ag aggregates were identified associated to the cell walls in the epidermis, the cortex and the endodermis of roots exposed to Ag-NP. A process of partial oxidation/dissolution of nanoparticles followed by a progressive chelation to GSH in planta was found in these roots. In Ag_2S-NPs treatment, Ag appeared colocalized with S forming aggregates mainly adhered to the root surface. We found evidence of Ag_2S-NPs reduction to metallic Ag in the root surface. For the plants exposed to $AgNO_3$, Ag was highly accumulated in the root epidermis and also formed spots of several micrometers in the intercellular space of the cortex. Speciation analysis indicated a process of Ag dissolution in the epidermis followed by Ag chelation to thiol and formation of metallic Ag in the root cortex. Phytotoxicity data (thiobarbituric acid production and quantitative real-time polymerase chain reaction) showed that, even if the three Ag treatments induced growth retardation in exposed plants, the toxicity mechanisms that induce this retardation are specific of each Ag source. Toxicity caused by the release of Ag+, represented by the $AgNO_3$ treatment, seemed to be mainly mediated by oxidative stress. Nanoparticles phytotoxicity may be due to both the release of Ag+ and to their high surface reactivity. Overall, the results show the complex interplay between nanoparticulate and ionic form of Ag, and that exposure to Ag nanoparticles induce a complex response possibly due to the multiplicity of Ag species in the plant. Such knowledge on the fate and impact of nanomaterials for plants, is necessary to better evaluate the risk associated to the use of these products.

State of the science on poly- and perfluoroalkyl substances (PFASs) in the environment and humans (II)

224

Factors influencing the water-suspended sediment partitioning and sediment levels of legacy and emerging fluoroalkylated substances (PFAS) along the salinity/turbidity gradient of a macrotidal estuary

P. Labadie, CNRS; G. Munoz, Université de Bordeaux; H. Budzinski, University of Bordeaux / UMR EPOC LPTC

Fluoroalkylated surfactants (PFAS) are organofluorine compounds that have been produced and used since the 1950s in numerous applications. Since the global distribution of perfluorooctane sulfonate (PFOS) in wildlife was revealed, PFOS and long-chain perfluoroalkyl carboxylates (PFCAs) have been of particular concern due to their potential for persistence, bioaccumulation, and toxicity, prompting international efforts to phase-out their production or propose more environmentally-sustainable alternatives. Since 2001, the science community has gained a better knowledge as to how long-chain PFASs enter aquatic environments (sources) and partition between water, sediments and biota (fate). However, knowledge gaps still remain to be bridged as regards the environmental behavior of legacy (e.g., PFOS, long-chain PFCAs) and substitution PFAS, especially at the land-sea interface. The question whether PFASs may be scavenged along the salinity/turbidity gradient of a macrotidal estuary is indeed of critical importance to predict their land-sea transport through river discharge into coastal waters. The present survey was conducted in the Gironde (SW France), targeting both legacy and substitution PFASs such as short-chain PFCAs, fluorotelomer sulfonates (FTSAs), and polyfluoroalkyl phosphate diesters (diPAPs). In this estuary, PFASs were ubiquitous albeit at low levels (ΣPFAS < 8.3 ng L^{-1} in the dissolved phase and < 3.3 ng g^{-1} in sediments). In the dissolved phase, ΣPFAS decreased near-linearly with salinity, being PFOS, perfluorohexane sulfonate (PFHxS) and perfluorohexanoate (PFHxA) the dominant congeners. In the maximum turbidity zone (suspended solids up to 2.6 g L^{-1}), the particle-associated fraction was almost consistently > 50 % for long-chain perfluoroalkyl acids (PFAAs), and could be as high as 30–34 % for short-chain PFCAs. Models of K_D partitioning coefficients were derived by integrating both particle-concentration and salting-out effects, and could be used in the future to implement transport models integrating hydrodynamic parameters to estimate PFAS mass budgets at the land-sea interface. Multiple linear regressions taking into account non-detects (data < LOD) provided insights into the relative influence of factors controlling PFAS sediment levels. In that respect, the organic carbon fraction (strongly correlated to sediment grain size) appeared as a more important controlling factor than distance from upstream sources for medium- to long-chain PFAS.

225
Perfluoroalkylated Substances in Oceanic Plankton
P. Casal Rodríguez, IDAEA-CSIC / Environmental Chemistry; Y. Zhang, University of Alberta; A. Reardon, University of Alberta / Department of Laboratory Medicine and Pathology; J.W. Martin, University of Alberta / Laboratory Medicine and Pathology; B. Gonzalez-Gaya, Institute of Environmental Assessment and Water Research / Environmental Chemistry; B. Jimenez, IQOG-CSIC / Instrumental Analysis Environment; J. Dachs, IDAEA-CSIC / Environmental Chemistry
Perfluoroalkylated substances (PFAS), including perfluoroalkyl carboxylic acids (PFCAs) and perfluoroalkyl sulfonic acids (PFSAs), are ubiquitous in the environment, reaching the remote oceans, and have been reported to induce harmul effects on terrestrial and aquatic organisms. PFAS bioacumulate and biomagnify in aquatic food webs, and even though there are previous studies on the occurrence of PFCs in biota, few of them report concentrations on the first levels of the aquatic food webs (phytoplankton and zooplankton). The objective of this study was to investigate the global oceanic occurrence of PFCA and PFSA in plankton samples, to elucidate the factors driving their occurrence, and to evaluate their bioaccumulation factors. The analysed seawater and plankton samples were obtained during the Malaspina circumnavigation campaign sampling the Pacific, Indian and Atlantic Oceans, and additionally, water and plankton samples were also obtained in the coastal Southern Ocean at Livingston Island (Southern Shetlands). SPFASs concentrations in ranged from 3 ng g_{dw}^{-1} to 60.9 ng g_{dw}^{-1}, with minimum concentrations in the Pacific and Southern Oceans, and maximum concentrations in the tropical south Atlantic. There was a significant linear correlation between concentrations of SPFAS in plankton and water ($R^2 = 0.45$, p-value< 0.01), which was driven by the two major analytes in this study (PFOS with $R^2 = 0.71$, p-value< 0.01, and PFHxS, $R^2 = 0.63$, p-value< 0.01). Additionally, the isomeric pattern and concentrations of PFOA (n, iso, 5m, 4m, and 3m) and PFOS (n, iso, 5m, 4m, 3m, and 1m) were quantified in plankton samples. PFOA total branched isomers (%br-PFOA) in plankton samples were highest in the Northen hemisphere, while PFOS total blanched isomers (%br-PFOS) followed the oposite pattern. This first report of PFAS concentrations in plankton samples from the global oceans shows that PFASs are ubiquitously found in oceanic plankton, and provides evidence that the concentration of PFSAs is closely coupled between seawater and plankton. In addition, we also provide a first assessment of isomer composition for PFOA and PFOS in plankton in the global oceans. The occurrence and bioaccumulation of PFAS is further discussed in terms of sources, transport and cycling.

Levels and maternal transfer of PFAS in Arctic hooded seal mother-pup pairs
R. Gronnestad, University of Oslo / Biosciences; G.D. Villanger, Norwegian Institute of Public Health; A. Polder, Norwegian University of Life Sciences / Department of Food Safety and Infection Biology; K.M. Kovacs, C. Lydersen, Norwegian Polar Institute; B. Jenssen, Norwegian University of Science and Technology / Biology; K. Borga, Department of Biosciences, University of Oslo / Department of Biosciences
Perfluoroalkyl substances (PFASs) are persistent contaminants that are present in the Arctic, and which have the capacity to bioaccumulate and biomagnify in food webs. There is a paucity of studies on the role of milk as a vector for maternal transfer of PFAS, and in particular in marine mammals, which have very lipid rich milk. The aim of the present study was to quantify PFASs in mother-pup pairs of hooded seals (*Cystophora cristata)* and to determine the potential role of milk as a vector in maternal-pup transfer of these compounds in this process. The hooded seal is a high trophic level predator in the arctic marine food web and is therefore susceptible to high exposure of contaminants. This species has a very short and intensive lactation period (3-4 days), enabled by the transfer of extremely lipid rich milk (>60% fat). This makes the hooded seal a good model to study maternal transfer of contaminants. Plasma and milk were collected from 15 mother-pup pairs in the marginal ice zone east of Greenland in 2008, and analysed for PFASs. Perfluorooctanesulfonate (PFOS) was the predominant PFAS in all samples (approximately 40% of ΣPFAS), and the levels were within the range of levels reported in similar studies on pinnipeds. Mean ΣPFAS concentrations were 66 ng/g ww in pup plasma, 36 ng/g ww in maternal plasma and 3.2 ng/g ww in the milk. Higher ΣPFAS levels in maternal plasma compared to the milk supports the concept that binding to plasma proteins limits their incorporation into milk. The individual PFASs differed in their transfer between mothers and pups depending on their carbon chain lengths, with the lowest transfer efficiency for the intermediate chained PFASs and higher transfer of both higher and lower chained carboxylates. The current study was the first to document PFASs in pinniped milk and in hooded seal plasma. We have confirmed maternal transfer of PFASs from hooded seal mothers to pups, and that this transfer likely takes place both via milk and placental transfer; the latter is thought to be the dominant pathway.

227
New concern on old substances - endocrine disrupting effects of PFAS
E. Fetter; A. Biegel-Engler, C. Staude, German Environment Agency; L. Vierke, Federal Environment Agency UBA / Section IV Chemicals; C. Schulte, Umweltbundesamt / Chemicals
Concerns for long chain per- and polyfluorinated alkyl substances (PFAS) have been identified due to their persistent, bioaccumulative and toxic properties. Successful regulatory activities are targeting the long chain PFAS due to these properties but also resulted in an increased use of short chain PFAS as “alternatives” by the industry. As a consequence, already today, short chain PFAS are found increasingly in different environmental media. Since they are less bioaccumulative but persistent, they might be spread out in the environment ubiquitously due to their mobility. Therefore, it is of importance to reveal concerns related to their presence in different environmental compartments in order to initiate regulatory measures. Recently, first studies on PFAS endocrine disruptive properties have been published in the scientific literature. Most of the studies using in silico or in vitro test systems. Only limited number of studies has been found in the public scientific literature using in vivo test systems. Hence, most information on endocrine effects could be attributed to the endocrine disrupting mode of action but not to the related adverse effects. While in vitro estrogen receptor binding studies are contradictory for PFAS, in vivo results give the first evidences on estrogen mode of action in fish for some selected perfluoroalkyl carboxylic acids and fluorotelomer alcohols. Several studies indicate interactions of PFAS with the thyroid hormone signaling. Effects assessed by far, are related to the binding of thyroid receptors, thyroid hormone transport proteins and alterations of genes related to thyroid hormone biosynthesis, transport and bioactivation. Unfortunately, aquatic in vivo assays are lacking for the short chain PFAS but the ones available for the long chain members indicating interaction with the thyroid hormone signaling. Only limited number of studies gives first indication on interaction with the glucocorticoid pathway. Although information on endocrine disruption properties of PFAS are mosaic and mostly provided by in vitro studies, the first evidences show that this aspect might require more attention, especially for the short chain PFAS that might be spread out in the environment due to their mobility. Since endocrine disruptors are considered as substances of equivalent concern under REACH, special attention should be given to these properties when assessing short chain PFAS.

228
Effects of perfluorooctane sulfonate and alternatives on long-term potentiation in rats in vivo
W. Liu, School of Environmental Science and Technology, Dalian University of Technology / School of Environmental Science and Technology; Q. Zhang, Y. Wang, H. Zhao, School of Environmental Science and Technology Dalian University of Technology
With limited but ongoing production and application of perfluorooctane sulfonate (PFOS), the toxicity of its alternatives is lack of evaluation. The present study evaluates the effects of PFOS and its alternatives on long-term potentiation, aiming to provide some evidence for their potential to affect cognitive ability. Targeted alternatives included perfluorohexane sulfonate (PFHxS), perfluorobutane sulfonate (PFBS), and chlorinated polyfluorinated ether sulfonate (F-53B). Different dosages of PFOS and alternative chemicals were given to rats via acute intracerebroventricular injection exposure. The input/output functions (IO), paired-pulse facilitations (PPF), and long-term potentiation (LTP) of the field excitatory postsynaptic potential (fEPSP) ampilitude *in vivo* were recorded. PFOS and alternatives exposure did not significantly affected the normal synaptic transmission, but inhibited LTP in hippocampus CA1 region in a dose-dependent manner. In addition, PFHxS and F-53B exhibit comparable potential to PFOS in disturbing LTP. The results suggested that acute exposure to PFOS and its alternatives resulted in the impairment of the synaptic plasticity by a postsynaptic rather than presynaptic mechanism. Besides, the fEPSP amplitude of baseline was reduced by F-53B but not by other compounds, indicating that F-53B might possess a different action mode. Therefore, further study was conducted to evaluate the effects of the chronic PFOS exposure during developmental period on LTP. The results found that LTP was repressed later in life by early PFOS exposure. Providing some electrophysiological evidence and potential mechanism of the neurotoxic effects induced by PFOS and its alternatives, the present study suggests further evaluation of their safety.

Alternative approaches to animal testing for ecotoxicity assessments

229
Comparison of two fish cell lines for the evaluation of model contaminants and PAH complex mixtures toxicity
P. Pannetier, C. Clérandeau, University of Bordeaux; J. Cachot, EPOC- Université de Bordeaux; B. Morin, University of Bordeaux
Fish are currently used models for the toxicity assessment of chemicals. The REACH Regulation and the European directive on the protection of animals used

for scientific purposes wish the establishment of alternative assays to animal experiments. In this concern, fish cell lines are being developed to provide fast and reliable results on the toxic and ecotoxic properties of chemicals while respecting ethical concerns about animal testing. Rainbow trout liver cell line RTL-W1, which is one of the best characterized cell lines derived from fish for mechanism-specific bioassays and Japanese medaka embryos cell line OLCAB-e3 were used to validate different toxicity assays (MTT, EROD and comet assay) on four model contaminants with different properties: B[a]P, PCB126, Cadmium and Methyl Methanesulfonate. In addition, these cell lines were used to analyze the effects of four polycyclic hydrocarbon (PAH) complex mixtures: *Arabian light* crude oil, refined oil from *Erika*, unleaded petrol and diesel oil. Whatever the bioassays and contaminants tested, dose-dependent effects were observed but with marked differences of sensitivity between cell lines. For the cytotoxicity endpoint embryonic cell line, OLCAB-e3, is more sensitive than trout cell line, RTL-W1 for the majority of compounds. On the contrary, for genotoxicity, the rainbow trout cell line is more sensitive than the medaka one. However, both cell lines give information about toxicity mechanisms of compounds. Our preliminary results confirmed the possibility of using cell lines to assess the toxicity of chemicals, including mixtures, especially in high throughput screening assays. Differences in sensitivity have been found between fish cell lines. It is therefore necessary to carefully select a cell line based on the mode of action and the nature of the studied toxic compound. Same compound will be tested on other alternative to animal experiment: fish embryotoxicity assay. Results will be compared with those obtained on cell lines.

Fish & Chips: Development of a novel in vitro system of the fish intestine

C. Drieschner, Eawag, Aquatic Research / Department of Environmental Toxicology; P. Renaud, EPFL / LMIS; K. Schirmer, Eawag / Environmental Toxicology

Fish are important test organisms in chemical risk assessment. One promising strategy of replacing expensive, time consuming and ethically questionable animal experiments with fish is the use of continuous cell cultures from rainbow trout. Our approach of recreating the intestinal microenvironment of fish *in vitro*, to study physiological responses towards toxicants, is based on the cell line RTgutGC and newly developed microchip technology. *In vivo*, the intestine is lined by a single layer of absorptive epithelial cells, which faces the intestinal lumen on one side and the inner of the body on the other. Herein, the basement membrane represents an ultrathin, highly porous substrate for the epithelial cells. *In vitro*, this delicate membrane is often mimicked with transwell integrated plastic membranes. However, these membranes are relatively thick, show low porosity and visibility of cells using light microscopy is not possible. Using standard microfabrication technology we were able to engineer an ultrathin, highly porous membrane as new cell culture interface. The new membranes are unique in terms of their high porosity and equally distributed nanopores. A single cell seeded on the substrate is in contact with ~3000 pores, while a cell on commercial membranes only faces ~20 pores. A great advantage of ultrathin membranes is their transparency which allows to follow cell growth over time with light microscopy. In addition, confocal microscopy through the membrane results in high quality images. For long term cell culture over 21 days we observed cellular polarization with basolateral actin stress fibers and apical tight junction formation. Non-invasive impedance monitoring over the culture period of 28 days revealed a strong increase in ohmic resistance within the first 24 hours, resulting from cell attachment. Thereafter, resistance increased slowly and steadily due to cell proliferation. Impedance was also used to on-line monitor the response of epithelial cells to toxicants (e.g. sodium dodecyl sulfate). A decrease in ohmic resistance was associated with a decrease in cell viability and disruption of barrier functionality. For ongoing studies we aim to establish a co-culture system of epithelial cells (RTgutGC) and fibroblasts (RTgutF) on chip. Moreover, we will integrate the microchip in a microfluidic bioreactor to allow for realistic, biologically relevant exposure and transport phenomena of chemical pollutants found in the aquatic environment.

In vitro to in vivo extrapolation of hepatic metabolism in fish: an inter-laboratory comparison of in vitro methods

K.A. Fay, University of Minnesota - Duluth / Biology; M.R. Embry, ILSI Health & Environmental Sciences Institute (HE; M. Bernhard, The Procter & Gamble Company / Env Stewardship and Sustainability; I. Bischof, Fraunhofer IME - Institute for Molecular Biology and Applied Ecology; J.W. Davis, Dow Chemical Company / Toxicology and Environmental Research and Consulting; J. Domoradzki, Dow Corning Corporation / Health and Environmental Sciences; M. Halder, European Commission Joint Research Centre / DG Joint Research Centre IHCP EURL ECVAM; J. Hu, The Dow Chemical Company / Toxicology and Environmental Research and Consulting; K.M. Johanning, KJ Scientific LLC / dba of Pura Vida Connections LLC; H. Laue, Givaudan Schweiz AG / Fragrances S T; D. Nabb, DuPont; J.W. Nichols, U.S. EPA / ORD NHEERL Mid Continent Ecology Division; H. Peterson, DuPont; C. Schlechtriem, Fraunhofer IME / Bioaccumulation and Animal Metabolism; H. Segner, University of Bern / Centre for Fish and Wildlife Health; L. van der Wal, OECD; J.A. Weeks, S.C. Johnson & Son, Inc. / Environmental Safety

Chemical biotransformation represents the largest source of uncertainty in chemical bioaccumulation assessments. Models of chemical bioconcentration in fish may be greatly improved by including biotransformation rates, as measured in vitro. Substrate depletion assays with trout hepatocytes or liver subcellular fractions (S9) have been successfully employed to this end. Regulatory use of these procedures, however, requires that they be evaluated to determine their reproducibility within and among laboratories. Building on previous work, a multi-laboratory ring trial was coordinated by the ILSI Health and Environmental Sciences Institute (HESI). The specific aims of the ring trial were to determine the reliability of these assays within and across laboratories, compare the performance of substrate depletion assays using the two biological systems, and support the development of an OECD test guideline (OECD Project 3.13). Six laboratories (Procter & Gamble, Fraunhofer IME, Dow Chemical, DuPont, KJ Scientific/SC Johnson, Givaudan) conducted substrate depletion assays for 6 test chemicals (pyrene, 4-*n*-nonylphenol, fenthion, cyclohexyl salicylate, deltamethrin, methoxychlor) using both trout liver S9 fraction and trout hepatocytes to determine in vitro intrinsic clearance ($CL_{in\ vitro,\ int}$). For the different test chemicals, the intra-laboratory agreement in $CL_{in\ vitro,\ int}$ averaged 14-22 %CV for the hepatocyte assays and 5-32 %CV for the S9 assays. The inter-laboratory agreement was somewhat higher, ranging from 23- 40 %CV for the hepatocyte assays and 11 -42% for the S9 assays. Extrapolation of the in vitro intrinsic clearance rates for each test system to in vivo intrinsic values resulted in good agreement (within 2x) for all test chemicals except pyrene (~5x difference). Much of the variability in the in vivo clearance predictions was further reduced upon incorporating blood flow limitations and protein binding algorithms into hepatic clearance predictions. As seen in previous studies, inter-laboratory variability was further reduced upon incorporation of in vitro rates into BCF prediction models. The results of this ring trial firmly establish the reliability of these methods and provide strong support for use of this information in modeled BCF assessments for fish.

Assay development based on the AOP network "thyroperoxidase and deiodinase inhibition leading to impaired swim bladder inflation"

E. Stinckens, University of Antwerp; L. Vergauwen, University of Antwerp / Zebrafishlab Dept Veterinary Sciences; A. Schroeder, US EPA / Water Resources Center; W. Maho, University of Antwerp Toxicological Center / Toxicological Centre Dept Pharmaceutical Sciences; B.R. Blackwell, ORISE; H. Witters, VITO / Applied Bio molecular Systems; R. Blust, Department of Biology; G.T. Ankley, U.S. EPA / National Health and Environmental Effects Research Laboratory; A. Covaci, University of Antwerp, Toxicological Center / Toxicological Center Dept of Pharmaceutical Sciences; D.L. Villeneuve, U.S. EPA / Mid Continent Ecology Division; D. Knapen, University of Antwerp / Zebrafishlab Dept Veterinary Sciences

The vast number of industrial chemicals has generated a strong focus on alternative test development for ecological risk assessment. Therefore, we are developing a non-animal testing strategy for the prediction of chronic aquatic toxicity including *in vitro* tests and *in vivo* ZFET (Zebrafish Embryo Acute Toxicity Test, OECD TG 236) assays. Our assay development process is based on using the adverse outcome pathway (AOP) framework to identify key events (KEs) that could be used to predict chronic toxicity. We developed an AOP network, encompassing thyroperoxidase (TPO) and deiodinase (DIO) activity inhibition, leading to decreased T4 (prohormone) and/or T3 (biologically active hormone) concentrations, impacting swim bladder development and inflation. The latter is considered an ecologically relevant adverse outcome as it affects feeding behaviour and predator avoidance, resulting in lower survival probability. For the assessment of AOP-specific KEs, we optimized *in vitro* assays to characterize the effects of a battery of environmental chemicals with suspected thyroid disrupting activity on TPO/DIO activity. Results were used to predict the impact on swim bladder inflation and validation was accomplished using 120 hours post fertilization (hpf) ZFET and 32 days post fertilization (dpf) FELS (Fish Early-life Stage Toxicity Test, OECD TG 210) experiments. Mercaptobenzothiazole (MBT), a compound identified as a TPO inhibitor, does not directly impair posterior chamber inflation at 120 hpf, while iopanoic acid, a DIO inhibitor, and propylthiouracil, which inhibits TPO and DIO, do. These results affirm our AOP network stating that embryonic TPO activity is not essential for posterior chamber inflation, because of the presence of maternal T4, while DIO activity is needed to activate maternal T4 into T3. However, both enzymes are needed to synthesize and activate THs at later developmental stages, so both TPO and DIO inhibitors were predicted to impair anterior chamber inflation. A FELS MBT exposure indeed resulted in impaired anterior chamber inflation at 21 dpf. Moreover, a relationship between T4 levels and anterior chamber surface further suggests an influence by THs on anterior chamber inflation. *In vitro* assays measuring the TPO/DIO inhibitory potential of compounds were optimized and used to screen a battery of relevant compounds. The results were successfully used to predict the impact on swim bladder inflation, which was validated using ZFET and FELS tests.

Ecological Threshold for Toxicological Concern (eco-TTC) - Assessing the potential of a new tool for environmental hazard assessment

A. Beasley, The Dow Chemical Company / TERC; M.G. Barron, U.S. EPA / Gulf Ecology Division; S.E. Belanger, The Procter & Gamble Company / Environmental Stewardship and Sustainability Organization; J. Brill, The Procter & Gamble Co. / Environmental Stewardship and Sustainability; D. De Zwart, RIVM / Centre for Sustainability Environment and Health; M.R. Embry, ILSI Health & Environmental Sciences Institute (HE; B. Farr, ILSI Health and Environmental Sciences Institute (HESI) / Health and Environmental Sciences Institute HESI; A. Kienzler, European. Commission - Joint Research Centre / IHCP System Toxicology Unit EURL ECVAM; H. Sanderson, Aarhus University Department of Environmental Science / Department of Enviromental Sciences; M. Halder, European Commission Joint Research Centre / DG Joint Research Centre IHCP EURL ECVAM; R. Hummel, U.S. EPA; T.J. Norberg-King, U.S. EPA / NHEERLMidContinent Ecology Division; R.M. Sternberg, U. S. EPA / Environmental Fate and Effects Division; J.G. Suski, U.S. Environmental Protection Agency / Safer Choice Program; P.W. Wilson, Sanofi U.S., Inc. / Health Safety and Environment

The ecological Threshold for Toxicological Concern (eco-TTC) is a new tool under development that summarizes the wealth of ecotoxicological information in the form of Predicted No-Observed Effect Concentrations (PNECs) on diverse chemical substances in the form of statistical (probability) distributions.
Eco-TTCs can be developed that allow prediction of untested chemicals based on structural attributes (categories), mode of action, or functional use. The approach may be useful for assessing chemicals at early tiers of the risk assessment process, provide hazard perspective on chemicals that lack QSARs, can be used to guide product development discussions, and assist read across or category justifications. The proposed eco-TTC is the statistically determined fifth percentile value for the distribution of PNECs for an assessed group. The eco-TTC approach has the potential to reduce the need for animal testing (fish) in many situations. In this talk we summarize the process that has been developed to quantify eco-TTCs and then bring this to life by providing a few examples. Fundamental to the development of eco-TTCs is the formation of a rigorous ecotoxicological database (transparent, high quality studies, traceable to the point of origin). A particularly interesting aspect of this work is segmentation of the data by mode of action and chemical categories. Non-polar and polar narcotic compounds comprise the vast majority of tonnage of chemicals in commerce and provide the first chance to assess the congruence of eco-TTC predictions and patterns with QSARs as well as environmental risk assessments built on empirical data submitted to REACH and other chemical management programs. Approximately 500 chemicals in the eco-TTC database have either a non-polar or polar narcotic mode of action and of these approximately one third have complete acute or chronic data sets (all three taxa). However, the derived PNECs are relatively randomly distributed with respect to application factors applied to the most sensitive taxon when ranked from lowest to largest PNEC. The eco-TTC for non-polar and polar narcotics is explored in depth. Additional category assessments (phenols, esters, reactive compounds, etc.) with sufficient information are under development. Based on the overall data set statements can be made about relative sensitivity of taxa and trophic groups can also be discussed. Eco-TTCs are seen as a promising addition to the toolkit of hazard assessment.

Biomonitoring of contaminants in the marine environment: integration of biological and chemical approaches

234

Developing tools for diesel biomonitoring in tropical coastal habitats of Brazil

A. Sardi, Akvaplan-niva; L. Sandrini-Neto, P. da Cunha Lana, UFPR; P. Renaud, L.A. Camus, Akvaplan-niva

Recent offshore petroleum exploration in Brazil has increased the risks of oil spills in tropical habitats. To better protect environmental health, improved oil-spill preparedness and response is needed. In order to identify tools for developing better biomonitoring strategies, we are currently assessing the efficacy of antioxidant biomarkers as post-spill monitoring tools. Our specific goals are 1) to establish a baseline of biomarker values for tropical species 2) to characterize the antioxidant biomarker response in two common species the clam *Anomalocardia flexuosa* and the polychaete *Laeonereis culveri* exposed to sediments spiked with diesel oil under laboratory conditions and 3) to evaluate the biomarker response after chronic exposure to diesel oil *in situ*. Specimens of *A. flexuosa*, the mangrove oyster *Crassostrea rhizophorae*, the snail *Neritina virginea*, the crab *Uca maracoani* and the catfish *Genidens genidens* were sampled in two different seasons, and at locations two locations, one contaminated and another control. Measured markers include CAT, SOD, GPx, GST and LPO. Multivariate analyses were employed to visualize results and a two-way PERMANOVA test was use to test for significant differences in the antioxidant response among species, levels of contamination and seasons. The interaction between season and contamination condition was significant, indicating that biomarker variation responds to complex settings. In the lab experiment, significant differences in antioxidant enzymatic activity depended on the sampling time after the exposure event. Changes in the enzyme activity were fast, with differences occurring between sampling separated only by 24h, proving that the time in which these endpoints are to be measured after a putative oil spill is of major importance. The overall pattern in the enzymatic response was species specific, showing that none of the enzymes measured can be expected to show the same pattern of response (inductive or inhibitory) for both species. A field validation study with chronic diesel oil exposure, to be conducted in early 2015, will include background variability as an informative modulator for oil exposure response at the cellular level. Data provided from this work will contribute significantly to the post-spill monitoring assessment tool-box in tropical waters.

235

The marine environment of Kuwait- an integrated monitoring programme to assess the impacts of pollutants

B.P. Lyons, Cefas Weymouth Laboratory; M. Devlin, James Cook University; A. Smith, Cefas / Ecotoxicology and Molecular Ecology; A. Al-Zaidan, H. Al-Sarawi, Kuwait Environment Public Authority

Threats to the marine environments of Kuwait, and the wider Gulf, are both evident and increasing, and the status of many aspects of the region's unique biodiversity are at record low levels. Like many of the other countries which comprise the Gulf Co-operative Council (GCC), Kuwait has undergone major economic, social and industrial development following the discovery of its oil reserves. This has led to a variety of contaminants being discharged directly to the marine environment, including petroleum hydrocarbons, metals, nutrients, and contaminated brine from desalination plants. Here we report the findings of a comprehensive marine monitoring programme, which along with collecting contemporary data, included an extensive review of a 30 year dataset (water microbial quality, metal pollution and nutrient inputs) to establish the historic baseline of pollutants within Kuwait. A present day assessment of the 'health' of the marine environment, in relation to chemical and biological contaminants, included the analysis of water, sediment and biota for a range of chemical contaminants including polycyclic aromatic hydrocarbons (PAHs), metals, polychlorinated biphenyls (PCBs) and polybrominated diphenylethers (PBDEs). In addition historic inputs of sewage contamination using sedimentary faecal sterol markers were assessed alongside conducting ecotoxicology screening of seawater samples and the assessment of biomarker response and histopathology in key sentinel species. The findings indicate that while Kuwait's marine environment has been subject to a wide array of pollution events, the actual levels of chemical contamination remains relatively low. However, sediment contamination hotspots associated with point sources of industrial contamination were evident at a number of locations around the coast. The assessment of histopathology in fish species indicated that lesions associated with chemical contamination were low when compared with other studies conducted globally. Sewage contamination continues to be a serious issue, with a number of coastal sites heavily contaminated. Linked to this was the observation that seawater samples displayed both acute toxicity and endocrine disrupting potential when screened with bioassay tests. Overall the data allowed 'health assessments' to be conducted at a number of sites and the findings are currently being used by the competent authorities in Kuwait to refine and redesign their national monitoring programme.

236

Is alkali labile phosphate (ALP) a suitable biomarker for endocrine disruption in marine mussels?

P. Sanchez Marin, L. Fernández-González, L. Mantilla-Aldana, University of Vigo / Ecology and Animal Biology; A.P. Diz, University of Vigo / Biochemistry Genetics and Immunology; l. vidal, ECIMAT

Alkali labile phosphate (ALP) is usually measured as a proxy for vitellogenin in fish and molluscs, the ALP method detects inorganic phosphate liberated from phosphorylated proteins like vitellogenin and others. In mussels, it has been measured either in gonad, hemolymph or digestive gland and used in both laboratory and field experiments as a biomarker of endocrine disruption. However, recent studies have shown that vitellogenin is only produced in the female gonad of bivalves and that the phosphorilated proteins measured by ALP in hemolymph correspond to extrapallial protein precursor and not to vitellogenin, that is absent in this fluid (Agnese et al. 2013; Oliveri et al. 2014). This work aims to demonstrate if ALP can still be used as a proxy of vitellogenin in the marine mussel *Mytilus galloprovincialis* when measured in the gonad, the primary site of vitellogenin production and accumulation. For that, several mussels were collected during two seasons representing different maturation stages (early gametogenesis and fully mature), sex and maturation stage were determined by histological analysis and vitellogenin was measured by two techniques: ALP and LC-MS/MS after separation by SDS-PAGE electrophoresis. Protein analysis by LC-MS/MS evidenced the presence of vitellogenin in female, but not in male gonads disregarding their maturation stage. On the contrary, ALP normalized both by protein or by tissue weight, was similar or even higher in males than in females, and did not change with maturation stage. Further protein analyses are currently being done in order to quantify and compare vitellogenin contents in mussel gonad's at different maturation stages and after being exposed to the synthetic estrogen ethinyl estradiol.

In situ toxicity testing using a nerite gastropod
M. Bighiu, Stockholm University / Environmental Science and Analytical Chemistry ACES; B. Eklund, Stockholm University / Department of Environmental Science and Analytical Chemistry; A. Eriksson-Wiklund, Stockholm University / Environmental Science and Analytical Chemistry ACES
Field studies are considered to be more relevant than laboratory tests, as they allow experimentation under natural conditions. Moreover, for some species, endpoints such as reproduction can only be successfully achieved *in situ*. Thus, the aim of this study was to observe the long-term effects of harbor water on a common snail in the Baltic Sea - *Theodoxus fluviatilis*. Harbors (including marinas) are well-known for accumulating pollutants due to poor water exchange. Antifouling paints are one of the main sources of pollution due to their continuous release of biocides into the harbor waters. Thus it is important to assess the sublethal effects of these mixtures of biocides and other contaminants, as they can be an early warning signal for a risk at population level. During two consecutive boating seasons we exposed caged snails in 2 or 3 marinas (2014 and 2015, respectively). The cages were immersed at 1 m depth at all sites and were periodically cleaned to ensure good water exchange. The reproduction of snails was assessed in terms of number of eggs laid in each cage after 2 or 4 weeks. During both years we observed significantly less eggs in all marinas compared to the reference sites (eg between 27- 99 % less eggs). The nutrients in the water were not limiting at any of the sites and therefore we reckon that the reduction in egg-laying in the marinas was due to other factors. Histopathology of the snails is on-going for detecting atrophy of the gonads or any other abnormalities. The marina with the lowest snail reproduction in both years also had the highest mortality, i.e. 6 times higher than at a reference site. The chemical analysis of the water revealed the highest copper and zinc concentrations in the respective marina but further evidence is needed to confirm that these metals are the main cause of the observed toxic effects. Analysis of metallothionein concentration in snails is on-going for measuring a direct biological response to metals such as copper and zinc. This unified investigation of effects at different levels of biological organization will likely help us quantify the contribution of metals vs other organic contaminants to the overall toxicity.

Biological effects of an offshore oil and gas installation on local fish populations: The Norwegian Water Column Monitoring programme
S. Brooks, NIVA / Ecotoxicology and Risk Assessment; D.M. Pampanin, IRIS; R.C. Sundt, Statoil
The biological effects of an offshore oil platform on local fish populations were assessed as part of the Water Column Monitoring (WCM) programme for 2014. The Njord A platform was chosen as the study location, which was not in operation and had no current discharge of produced water. Demersal fish species were targeted since they were believed to be less likely to migrate away from the platform than pelagic fish. By targeting organisms deeper in the water column and selecting a platform currently not in operation, the impact of drill cuttings and other sediment sources including leakages from well deposits were the main sources of contamination. Wild fish including ling (*Molva molva*), tusk (*Brosme brosme*), redfish (*Sebastes* sp.) and saithe (*Pollachius virens*) were caught with baited rod and line from within the 500 m safety zone of the Njord A platform during the summer of 2014. Reference fish were caught on a separate research cruise by trawling from a region of the Norwegian Sea less impacted by oil and gas activities. Contaminant body burden and a suite of biological effects endpoints were measured in all fish groups and included DNA adducts, DNA strand breaks by comet assay, acetylcholine esterase (AChE) inhibition, ethoxyresorufin 0-deethylase (EROD), vitellogenin (VTG), lysosomal membrane stability (LMS), liver and gill histopathology, PAH metabolites, and PAH body burden. The biomarker data were integrated using the integrated biological response index (IBR/n). Despite low and/or undetected concentrations of PAH and PAH metabolites in fish fillet and bile respectively significant responses in AChE, comet and DNA adducts were found. The biomarker responses indicated exposure to both neurotoxic and genotoxic chemicals in fish inhabiting the lower water column with influence from sediment sources around the Njord A platform. Integration of the biomarker responses (IBR/n) found that all four fish species that were caught from around the platform had markedly higher IBR/n values than their respective reference population. The study shows the advantage of using a suite of biomarkers for assessing the biological effects of low concentrations of complex mixtures with biological effects observed despite low concentrations of PAH measured.

239
The Integrated Biomarker Response: a suitable tool to evaluate toxicity of metal-based nanoparticles
S. Devin, LIEC - Université de Lorraine - CNRS / LIEC CNRS UMR; P. BUFFET, The Cobalt Development Institute; A. Chatel, Université Catholique de lOuest / Sciences Environnement; H. Perrein, Université Catholique de lOuest / MMS; C. Mouneyrac, Université Catholique de lOuest / UNAM Université Nantes Angers Le Mans Mer Molécules Santé MMS
Nanotechnology is a much promising field of science and technology with applications in a wide range of areas such as electronics, biomedical applications, bioremediation, energy, cosmetics, water treatment. Among engineered nanoparticles (ENPs), metal-based ENPs comprise the largest number of ENPs such as silver, gold, copper oxide (CuO), zinc oxide (ZnO), cadmium sulfide (CdS) nanoparticles. The toxicity of metal-based NPs may be either due to their specific physical characteristics as NPs or to the specific toxicity of metals released from NPs under environmental conditions. In this study we evaluated toxicity effects of ENPs (Ag, Au, CuO, CdS, ZnO) and their ionic control part on two endobenthic species: the ragworm *Hediste diversicolor* and the bivalve mollusc *Scrobicularia plana*. The selected exposure concentrations for Cu, Ag, and Cd (10 $\mu g.L^{-1}$) were chosen considering concentrations reported for each metal in highly contaminated marine environments. For Au, because this metal is very inert, the concentration (100 $\mu g.Au\ L^{-1}$) was chosen in order to induce some biological responses. For ZnO NPs, we selected exposure to 3 mg $^{67}ZnO\ kg^{-1}$ sediment since this level is a realistic prediction of the environmental concentration in sediments (Tiede et al., 2009). The implementation of a suite of complementary biomarkers as early warning signals of the presence of contaminants has been successfully applied to provide integrated information on the toxicity of ENPs in aquatic species. A common challenge in multibiomarkers studies is to go beyond an independent interpretation of each one, and to really assess a global response of individuals. The aim of the present study was to test the suitability of the Integrated Biomarker Response (IBR) in both species exposed to the different metal-based ENPs studied or to their soluble metal counterpart to provide efficient and easy tools for environmental managers. We evidence that metal-based NPd lead to an overall difference in biological responses from the control and their soluble counterpart. The IBR could thus be considered as an efficient tool to transfer some research results to stakeholders.

Environmental risk assessment of chemical mixtures: the steps ahead (I)

240
Applying mixture toxicity modelling to assess the contribution of detected chemicals to in vitro effects: An example from the Danube River
P.A. Neale, Griffith University / Smart Water Research Centre; S. Ait-Aissa, INERIS / Ecotoxicology Unit; W. Brack, Helmholtz Centre for Environmental Research UFZ / EffectDirected Analysis; N. Creusot, INERIS; M.S. Denison, University of California / Department of Environmental Toxicology; B. Deutschmann, RWTH Aachen University / Department of Ecosystem Analysis ESA; K. Shao, RWTH Aachen University / Department of Ecosystem Analysis ESA; B.I. Escher, Helmholtz Centre for Environmental Research UFZ / Cell Toxicology
Surface water can contain a diverse range of organic micropollutants stemming from a number of sources. Targeted chemical analysis alone is unable to detect all micropollutants present and *in vitro* bioassays can be applied complementary to assess the biological effects of complex environmental mixtures. The aim of this study was to test the hypothesis that the *in vitro* effects in large human-impacted rivers are primarily driven by the mixture effects of many chemicals, rather than being dominated by a particular chemical. In this study a suite of bioassays indicative of activation of the aryl hydrocarbon receptor (AhR), activation of the pregnane X receptor (PXR), activation of the estrogen receptor (ER), adaptive stress responses to oxidative stress (Nrf2), genotoxicity (p53) and inflammation (NF-κB) and fish embryo toxicity were applied to large volume solid phase extracted (LVSPE) samples from the Danube River. This was complemented with targeted chemical analysis of 272 chemicals, with available effect concentrations for the detected chemicals collected from the literature or the US EPA ToxCast database. The contribution of detected chemicals to the *in vitro* effects was assessed using the bioanalytical equivalent concentration (BEQ) concept. Available effect concentrations for between 0 to 13 detected chemicals were found for the different assays. Up to 80% of ER activation was explained by five detected chemicals, with the hormone estrone and the phytoestrogen genistein contributing significantly, while up to 71% of AhR activation could be explained by three chemicals. In contrast, less than 0.2% of the effect was explained by the detected chemicals for PXR activation, oxidative stress response, p53 response and fish embryo toxicity. As a significant fraction of the effect could not be explained by detected chemicals, this study emphasises the importance of applying bioanalytical tools along with chemical analysis for water quality monitoring. The study was limited by the availability of effect concentrations for the detected chemicals and consequently further fingerprinting of water pollutants is recommended.

241
Comparison of approaches to assess the risk of micropollutants in Swiss

streams impacted by treated wastewater

N. Munz, L. Melo, B. Spycher, U. Schönenberger, Eawag / Environmental Chemistry; M. Reyes, F. Burdon, Eawag / Aquatic Ecology; D. De Zwart, RIVM / Centre for Sustainability Environment and Health; M. Junghans, Ecotox Centre Eawag-EPFL; H. Singer, C. Stamm, J. Hollender, Eawag / Environmental Chemistry

Micropollutants can enter surface waters through various pathways of which wastewater treatment plants (WWTP) and diffuse inputs from agricultural areas play a major role. A multitude of substances are present at concentrations in the ng/l-µg/l range, sometimes close to ecotoxicological relevant values which may induce adverse effects on aquatic organisms. In this study we assess the influence of the coverage of the chemical screening on the predicted risk using different risk assessment approaches and compare it with the observed impact on macroinvertebrates. Grab samples were taken upstream, downstream and at the effluent of 24 different WWTP (12 in 2013 and 12 in 2014). Samples were measured with liquid chromatography high resolution tandem mass spectrometry after offline or online solid phase extraction. Data was analysed for 57 organic micropollutants relevant for Swiss surface waters. For one time point of each campaign an additional comprehensive target screening of over 400 substances was conducted. Risk was assessed with two approaches: i) risk quotient (RQ) approach based on environmental quality standards, and ii) multi-substance potentially affected fraction (msPAF) predicting toxic pressure for aquatic organisms. Comparison with macroinvertebrate data was conducted using the $SPEAR_{pesticide}$ index. The exposure patterns showed expected trends, with higher concentrations downstream than upstream, especially for wastewater borne substances. The chronic RQ of the substance selection was above 1 at more than 15% of the upstream and 95% of the downstream sites. In many cases 4 to 5 single substances explained 95% of the risk; mostly including diclofenac, diuron, and often diazinon. The same substances were in many cases also the drivers of the toxic pressure for the msPAF approach. The comparison between the extended screening data set and the substance selection showed no clear difference using the RQ approach, but increased clearly acute toxic pressure applying the msPAF approach. However, acute toxic pressure remained in the low percentage range (max. 2.3%). The $SPEAR_{pesticide}$ index showed for all sites slightly lower values downstream than upstream and correlated with the fraction of wastewater. The findings indicate an influence of micropollutants discharged from WWTP on aquatic macroinvertebrates. However, the prediction of risk can change substantially depending on the coverage of the chemical data set and the risk approach applied.

242

Genotoxic and Ecological risks of river contamination for wild fish populations

R. Santos, A. BESNARD, Centre d Ecologie Fonctionnelle et Evolutive / Biogéographie et Ecologie des Vertébrés; S. BONY, INRA - CNRS / UMR LEHNA USC INRA IGH ENTPE; W. SANCHEZ, Institut National de l Environnement Industriel et des Risques / Unité décotoxicologie in vitro et in vivo; A. DEVAUX, INRA-CNRS / UMR LEHNA USC INRA IGH ENTPE

Water pollution by a wide range of substances is considered as one of the main threat to explain fish declines observed worldwide. To reach the good status of European water bodies, the European Water Framework Directive requires the monitoring of the chemical and ecological status of surface water bodies. In this context, biomarkers are considered as complementary to chemical and ecological analysis providing evidences of pollution driven biological defects at the individual scale. In this purpose, the first objective of this workwas to assess a battery of biomarkers on wild sticklebacks (*Gasterosteus aculeatus*). Furthermore, as environmental managers need to know if biomarker responses to environmental contamination are related to ecological risks for fish populations, the second objective aims at studying the relationship between a genotoxicity biomarker response in wild fish germ cells and reproductive impairment. Finally, an integrative approach was investigated gathering three Lines of Evidence (LOE): *i)* chemical analysis, *ii)* biomarker responses as early warning signals of contamination impacting individuals and *iii)* the Fish Based Index as an indicator of fish communities "health status" in French rivers to assess ecological risks for fish populations. Mature male sticklebacks were sampled in sites under contrasted chemical pressures to assess xenobiotic biotransformation, oxidative stress, neurotoxicity and genotoxicity biomarkers. Fish testis were also removed to collect spermatozoa, perform *in vitro* fertilization, assess the level of primary DNA damage in sperm and subsequent progeny survival. Biomarker responses showed correlations between genotoxicity, biotransformation and oxidative stress biomarkers, and discriminate sites under urban pressures. In the contaminated sites, significant lower probabilities of progeny survival were found compared to the reference site as well as a correlation between the level of paternal DNA damage in sperm and progeny survival, thus highlighting potential long-term population defects. Finally, the three LOEs investigated together provide more valuable information to assess ecological risks than using only individual LOE. When chemical and ecological indexes did not draw a clear conclusion, the use of biomarker analyses as the third LOE was relevant to make a diagnostic of the river contamination and of biological impacts.

243

Mixture risk assessment for surface waters: Comparative assessment of current approaches for assessing the environmental risk in five Swiss catchments

M. Junghans, Swiss Centre for Applied Ecotoxicology EAWAG - EPF / Ecotox Centre; T. Doppler, Plattform Wasserqualität VSA; I. Wittmer, Plattform Wasserqualität VSA, c/o Eawag; I. Werner, Swiss Centre for Applied Ecotoxicology / Department of Anatomy Physiology and Cell Biology

On 01.01.2016 a new water protection ordinance enters into force in Switzerland. In addition to introducing environmental quality standards (EQS) for single substances it allows for the consideration of mixture toxicity in water quality assessments as well as the initiation of measures if a surface water body is at risk of being ecotoxicologically impaired by a mixture of substances. Such measures can be taken even if no single substance EQS is exceeded. In the near future a guidance document will be developed that provides simple but sound methods for assessing the environmental risk of contaminant mixtures in surface waters. For this purpose, the current methods for mixture risk assessment were compared using data from a Swiss surface water monitoring study and chronic EQS proposed for Switzerland. The $\mathbf{RQ_{STU}}$ predictions always turn out higher than the simple sum of all individual RQ. Most likely, this is due to the extrapolation of the chronic mixture RQ from acute mixture toxicity predictions by using an AF of 1000. The lowest mixture RQ resulted using a method based on similarity of action ($\mathbf{RQ_{same\_MoA}}$). Since mixture RQ were restricted to substances for which concentration additivity had experimentally been shown, only three mixture RQ groups were assessed: (i) photosystem II inhibitors (triazine and phenylurea herbicides), (ii) inhibitors of very long chain fatty acids (chloroacetanailide herbicides) and (iii) herbicides with auxin action (phenoxy acids). The $\mathbf{RQ_{EQS\_Taxa}}$ method based on identifying the most sensitive trophic level(s) is likely to overestimate the mixture risk if dominant substances have different target taxa within the trophic level. However, the quantitative differences between the methods become marginal, if not all substances present in the sample are analyzed or detected. This was shown by taking passive sampling results for pyrethroids into account, showing that the RQ can be two orders of magnitude higher. All mixture RQ indicate that a risk assessment based on single RQ will understimate the actual risk. However, the current methods for mixture risk predictions still have some shortcomings. For regulatory purposes a combination between the $\mathbf{RQ_{same\_MoA}}$ and the $\mathbf{RQ_{EQS\_Taxa}}$ method seems to be promising. This may define the range of the actual mixture risk. Furthermore, it is important to include highly toxic compounds which are used in the watershed in any risk analysis.

244

Using prospective assessment to assess mixtures in municipal wastewater effluents

J.M. Diamond, Tetra Tech, Inc.; J. Tolls, Henkel AG & Co. KGaA; J. Snape, AstraZeneca UK Ltd. / AstraZeneca Global Environment; S.D. Dyer, The Procter & Gamble Company / Environmental Stewardship and Sustainability Organization

Municipal Waste Water treatment plants (WWTP) can be a source of "down the drain" chemicals that are targeted by diverse regulatory agencies concerned with potential environmental effects of these chemicals both independently and as mixtures**.** For the prospective assessment, the chemical mixture is based on domestic activities that are an important source of the chemical mixtures in municipal wastewaters. Starting with activities associated with domestic emissions of chemicals, we identified key products that are used and representative chemicals of those uses. Chemicals were selected based on their reported importance in ecological risk assessments and availability of loading and effects information in Europe. We evaluated a scenario in which a WWTP receives only domestic waste from a fairly small population in order to separate domestic wastewater mixture effects from other influences (e.g., urban stormwater). Chemical loadings to the WWTP were identified based on per capita per day information. Removal rates for each contaminant were based on their physicochemical and biodegradation properties, as well as 3 types of treatment (trickling filter, activated sludge, and advanced oxidation), to determine predicted effluent chemical concentrations (PECs). PECs were compared with predicted no effect concentrations available from the literature. Concentration addition was used to estimate the mixture risk for each scenario. Given activated sludge or better treatment, very few of the representative chemicals individually presented a risk to aquatic life even when PECs were increased over 10-fold. Given the chemicals used in this analysis and a concentration addition approach, mixture risk for the activated sludge treatment with or without the addition of advanced oxidation was driven by very few chemicals: galaxolide, EE2, sulfomethoxazole, and carbamezapin. These chemicals have different modes of action and when evaluated using response addition indicated little or no mixture risk given this analysis. Trickling filter treatment resulted in much greater potential for mixture risk in our analyses. Scenarios such as those used here can provide testable hypotheses for studies that include the use of biomonitoring or retrospective-based mixture assessments.

245

Predictability of the Aquatic Toxicity of Realistic Mixtures in Wastewater

Effluents and Their Risk Assessment
A. Coors, ECT Oekotoxicologie GmbH; F. Sacher, DVGW-Technologiezentrum Wasser; U. Kuehnen, Federal Environment Agency
The concept of Concentration Addition (CA) is widely accepted as a default approach for predicting combined toxicity of mixtures of chemicals. However, it can only be applied to mixtures of clearly defined components for their clearly defined mass proportions in the mixture, which limits its applicability to a routine risk assessment of highly complex and variable wastewater effluents. In order to explore the relevance of a mixture assessment compared to a single-substance assessment of residues in wastewater effluents, mixtures of up to ten substances were assessed at two different concentration ratios, including the experimental verification of their predicted toxicity in the absence and presence of wastewater background. The mixtures were tested at an effect-based ratio and at an exposure-based ratio that resembled a realistic mixture scenario. The toxicity of the mixtures could be reasonably well predicted for chronic endpoints both in green algae and in *Daphnia magna*. There was rather a slight tendency to overestimate mixture toxicity by the CA concept than to underestimate it, which demonstrates that the CA approach would be predictive for a mixture risk assessment without being over-protective. The predictability of the mixture toxicity was not influenced by wastewater effluents, i.e. by the presence of other substances at very low concentrations. The presentation will also compare preliminary risk assessments based on measured environmental concentrations (MEC) and predicted environmental concentrations (PEC) and on chronic endpoints of single substances as well as mixtures together with assessment factors for each test organism. In addition, preliminary predicted no effect concentrations (PNEC) will be derived for single substances and the mixtures, and they will be compared to summed MEC and PEC, which will demonstrate the difference for such mixture assessments conducted seperately for each trophic level or across trophic levels.

Fate and Effects of Metals: Regulatory and Risk Assessment Perspective

246
Retrospective monitoring of butyltin in fish and mussels from German marine and freshwaters
G. Radermacher, B. Knopf, Fraunhofer IME Institute for Molecular Biology and Applied Ecology / Environmental Specimen Bank and Elemental Analysis; M. Paulus, Trier University; J. Koschorreck, Umweltbundesamt; H. Ruedel, Fraunhofer IME - Institute for Molecular Biology and Applied Ecology / Environmental Monitoring
Tributyltin compounds (TBT) and their degradation products dibutyltin (DBT) and monobutyltin (MBT) have been proven to have strong ecotoxicologically effects on aquatic organisms (e.g. imposex of neogastropods, shell malformations of mussels). Therefore, a ban of TBT-containing antifouling coatings for small vessels under 25 m was imposed by the European Commission in 1989 (89/677/EWG) as a first measure. Since 1st January 2003, the usage and distribution of antifouling preparations containing organotin compounds is prohibited by the Commission Directive 2002/62/EG. Furthermore, in 2008 this ban was extended to EU-foreign flagged vessels. A retrospective monitoring of organotin compounds (including TBT, DBT and MBT) in archived freshwater and marine biota samples from the German environmental specimen bank (ESB) has been carried out earlier. The time series for butyltin concentrations in muscle tissue of freshwater fish (bream, *Abramis brama*) and marine fish (eelpout, *Zoarces viviparus*) as well as in marine mussels (*Mytilus edulis)* tissue were extended from 2003 to 2011 and samples from 2012/2013 are under investigation. The marine samples were collected from the North and the Baltic Seas, and the freshwater samples from the German rivers Elbe, Danube, Rhine, Mulde, Saale, Saar as well as from Lake Belau. After digestion, derivatization and extraction, trace levels of organotin compounds in the pooled and homogenized biota samples were analyzed by a validated sensitive SID-GC/ICP-MS method (species specific isotope dilution - gas chromatography - inductively coupled plasma-mass spectrometry). The results of this project allow answering the following questions: 1) Does the ban of organotin compounds as antifouling agent show positive effects on the butyltin concentration in aquatic biota? 2) Are there any differences in concentrations between the various sample sites and the various biota samples? 3) Are there any temporal trends in the concentrations of TBT, DBT and MBT?

247
Determination of water quality criteria for uranium that account for bioavailability in freshwaters
L. Fevrier, R. Gilbin, K. Beaugelin-Seiller, J. Garnier-Laplace, IRSN / PRPENVSERIS
Uranium (U) is a chemo- and radio- toxic substance of concern for the aquatic environment, with potential releases to freshwaters due to e.g., mining, processing and waste disposal. In France, a 'generic' Predicted No Effect Concentration (PNEC) for freshwater ecosystems has been set to 0.3 μg/L of dissolved U in the water column in addition to the background, based on an exhaustive review of available ecotoxicity data and the use of assessment factors. However, as many other metals, it is well known that U toxicity depends on its bioavailability which is in turn mainly driven by its speciation. For such elements, the last European guidance for deriving Environmental Quality Standards recommends now explicitly to take into account their bioavailability. Therefore, we developed a method based on theoretical simulation of U geochemical speciation in freshwaters (VMinteq v3.0, considering U complexation with dissolved organic matter and with alkaline earth and carbonate ions). Based on the assumption that the bioavailable species of U were UO_2^{2+}, $UO_2(OH)^+$, $UO_2(OH)_2$ and UO_2CO_3, a statistical regression tree analysis was performedto identify physico-chemical domains representative of French freshwaters where different PNEC might apply. Combining these first results to the available chronic U ecotoxicity data for each physico-chemical domain identified allowed us to derive four PNEC values (ranging from 0.3 to 30 μg/L) conditional to four physico-chemical domains that differ by their alkalinity (cut-off at 75 mg HCO_3^-/L), pH (cut-off at 7.5) and DOC content (cut-off at 6 mg/L). These findings were formalised in a determination tree. Further analyses were performed to evaluate the robustness of this tree and its domain of applicability. These conditional PNEC values for freshwaters could be used as a refined step in any ecological risk assessment for uranium. However, their applicability in any monitoring programme would need some adaptation in the monitoring practices: not only the dissolved fraction of uranium, but also the influent physico-chemical parameters (pH, alkalinity, DOC) should be measured together, with a sufficient accuracy and sensitivity.

248
A new approach to diagnosing the ecological effects of metal-contaminated sediment in natural systems
J.F. Murphy, Queen Mary University of London / School of Biological and Chemical Sciences; J.I. Jones, QMUL / School of Biological and Chemical Sciences; P. Rainbow, The Natural History Museum / Dept of Zoology; K. Spencer, Queen Mary University of London / School of Geography; A.L. Collins, Rothamsted Research, North Wyke; A. Moorhouse, the Coal Authority; V. Aguilera, DEFRA; P. Edwards, Southern Illinois University Carbondale / Zoolog; F. Parsonage, DEFRA; H. Potter, Environment Agency; P. Whitehouse, Environment Agency / Evidence
Pollution from abandoned metal mines is a serious impediment to rivers meeting the water quality targets set out by the EU Water Framework Directive. Recently, there has been recognition that managing these risks requires approaches to setting environmental guidelines that are based on a consistent definition of exposure in systems where bioavailability may vary, thus allowing more robust and useful ecological effect thresholds to be identified. We have used a new approach to relate the levels of toxic metals in sediments affected by mining to ecological damage based on bioavailability. The concept is to use widespread biomonitor species as chemical probes for bioavailable metal, and to relate this measure of metal stress to variation in invertebrate community composition (a WFD-compliant measure of ecological condition). This approach bridges two established methodologies that are traditionally used independently (community-level field observations and laboratory toxicology). We selected 99 river sites in England and Wales, across 20 spatially-independent, replicate river catchments impacted by metal mining. Within each catchment, sites were located upstream and downstream of abandoned mine facilities. At each site we sampled the macroinvertebrate community, collected biomonitor specimens for metal bioaccumulation analysis, and collected a fine sediment sample for metals content, organic carbon and particle size analysis. Using multivariate ordination techniques we then quantified the response of the macroinvertebrate community to variation in metal bioavailability, having first taken into account the confounding effects of other environmental factors. We identified the position of taxa across the gradient metal bioavailability, providing the basis for a new diagnostic metric to metal stress in rivers. The new metric was tested on an independent dataset drawn from existing data sources. Our aim is to provide a WFD-compliant method for detecting where contaminated sediments are causing ecological impacts.

Ten years on: Soil screening values for ecological risk assessment in the UK
G. Merrington, wca consulting; E. Stutt, O. Tran, WCA Environment Limited; I. Matin, Environment Agency England and Wales; D. Ashton, Environment Agency
A presentation on the "Use of soil screening values for metals for ecological risk assessment in England and Wales" was made at SETAC Europe in 2006. Since then, both scientific knowledge and regulatory priorities have changed in the UK in regards to soils and ecological protection. This presentation, 10 years on, provides an outline of those key changes and demonstrates how the continued practical and pragmatic application of complex scientific concepts can deliver solutions to regulatory challenges that face many in Europe and across the globe. The previous presentation focussed upon trace elements and in particular the implementation of a bioavailability framework to derive soil screening values (SSVs), to provide a generic screening tool to 'rule out' the further assessment of potentially contaminated sites. Just 10 soil screening values (SSVs) for prioritised chemicals were derived at the time. Regulatory priorities have now changed from contaminated land, to assessment wastes destined for recovery to land. SSVs are needed for many more and different chemicals that 10 years ago. However,

through the use of new guidance, the ECHA dissemination portal and industry collaborations SSVs have been devloped that utilise new data and research findings. This presentation will show that the lag between scientific developments and regulatory implmentation can be relatively short. Changing regulatory needs can keep pace with scientific developments. \n

Assessing the integrated terrestrial ecotoxicity of Cu and Ni species for life cycle assessment (LCA)

A. Yadghar, CIRAIG - École Polytechnique de Montréal / Chemical engineering department; C. Bulle, CIRAIG - ESG - UQAM / Strategy   corporate social responsibility; L. Deschenes, Ecole Polytechnique de Montreal / Genie Chimique

Life cycle assessment (LCA) validity of metals toxicity can be significantly affected by bioavailable metal fraction. The bioavailable fraction of Copper (Cu) and Nickel (Ni) for world soil types are calculated using WHAM 7 geochemical speciation model. Applicability of WHAM model for soils using their globally available properties (texture, pH, cation exchange capacity, and organic matter content) is examined and verified with soil field data and compared with an empirical regression method. The results obtained from WHAM 7 show that the model is able to calculate bioavailable fraction of Cu and Ni with uncertainties of less than two and three orders of magnitude, respectively, for a wide range of soils distributed globally. It is in better match with the experimental data in term of absolute value than the empirical regression results. To address this variability, 518 archetypes and 13 groups of archetypes are created to show the global distribution of obtained BF values. Moreover, BFs ranking was compared and the soluble Cu and Ni Spearman rank correlation coefficients showed a significant correlation between BFs obtained by WHAM and BFs calculated by the regression method. The BFs included in the calculation of CFs for Cu and Ni have been applied in terrestrial ecotoxicity and the level of regionalization required to adequately represent the spatial variability of CF has been defined. The obtained results from two different versions of the model (WHAM 6.0 and 7) were also compared for Zinc (Zn) to see whether the updated database of the model may change the results. This study validates using WHAM as a tool to study Cu and Ni bioavailable factor in global soils since the results cover a considerable range of world soils. This research will not only obtain regionalized CFs including Cu and Ni speciation in terrestrial ecotoxicity directly applicable in the current LCA methods, but also will show that it is possible to use geochemical models for large scale speciation in soil. We applied WHAM 7 for Cu and Ni to determine the BFs in soils to validate this approach with measured speciation data in term of absolute value and ranking and to be sure our big effort of modelling with warm is worth it. We showed it brings more appropriate answer than the regression method.

Quantitative risk assessment of mercury contamination to ecosystem in a mercury mining area

Y. Lin, Norwegian Institute for Water Research NIVA; G. Qiu, Institute of Geochemistry Chinese Academy of Sciences; H. Braaten, Norwegian Institute for Water Research NIVA; X. Feng, Institute of Geochemistry Chinese Academy of Sciences; T. Larssen, Norwegian Institute for Water Research NIVA

Wanshan Mercury Mining Area (WMMA) which is located in Southwest China has a long history of Hg exploration and smelting. Hg contamination has been a serious local problem for both human and environment for decades. The risks of Hg for human health have been reported in WMMA by several studies, and dietary intake rather than inhalation has been identified as the main exposure pathway for the local residents. However there has been less focus on the risk of Hg contamination on the ecosystem. The scope of this study is therefore aimed at quantifying the risk related to Hg pollution from an ecosystem perspective. The endpoints of the assessment will be plants and biota rather human. This study aims at developing a site specific index system to identify the risks of Hg contamination on major biota species (rice, invertebrates and birds). The exposure level in this study is determined by direct sampling and measurement of Hg concentrations in different references species at WMMA (soil, rice, earthworm, grasshopper, spider and bird samples were collected). Total Hg concentration is selected as proxy for comparing the concentration levels. No adverse effect concentration (NOAEL) is used as the risk assessment benchmark for the different species. Risk quotients (RQ) are then derived based on comparing the Hg concentrations in each species with benchmark values. Four levels of risk were proposed based on RQ values: Level 1: Background. If all RQ values are smaller than 1, and RQ are smaller than reference site, the species is then considered to be living under a similar condition as in the background site. Level 2: Minimal risk. If all the RQ values are smaller than 1, the species is then considered having minimal risk. Level 3: Moderate risk. It is possible that RQ of tissue concentration is smaller than 1, but RQ of diet is bigger than 1. This indicates that the species is having a risky diet, while tissue concentration has not reached risky level. Level 4: High risk. If RQ based on tissue concentration is greater than 1, it can be confirmed that the species is at risk. The plan for remediation at WMMA is under development with local authority, the outcome from the risk assessment will then supply important basis for the remediation method development, and possible measures to reduce the risk will be then proposed based on the results.

Higher tier tests in the risk assessment of plant protection products (II)

252

An SSD-based investigation of the relative sensitivity of Daphnia magna - Implications for risk assessment

M. Gustavsson, University of Gothenburg; T. Backhaus, University of Gothenburg / Department of Biological and Environmental Sciences

The species sensitivity distribution can be used to quantify the spread in sensitivity between different organisms. A large width of a distribution implies that there is a large difference between the most and the least sensitive species tested. Currently approximately 30% of the PNEC's from the single substances registered under REACH can be traced back to *Daphnia magna*. In order to determine whether the current risk assessment practice is protective, we compared the sensitivity of *Daphnia magna* to the sensitivity of other aquatic invertebrates. Ecotoxicity data were initially collected from the US EPA database ECOTOX. The data was thereafter filtered and only those compounds that contained acute toxicity data (1-7 days) from laboratory studies performed on aquatic invertebrates were kept. Finally the species sensitivity distributions were fitted using the R package "drc" for all compounds where 8 or more species had been tested. In total 157 species sensitivity distributions could be generated. The results show that the sensitivity of *Daphnia magna*, in relation to other tested aquatic invertebrates, varied randomly. The median factor between the most and the least sensitive aquatic invertebrate for each individual compound is estimated to be around 1300. The species sensitivity distribution for three specific compounds show that 2.3% (Temephos), 46.4% (Toluene) and 93.75% (Endosulfan) of all aquatic invertebrates are assumed to be more sensitive than *Daphnia magna*. The difference between the relative sensitivity of *Daphnia magna* for these three compounds demonstrates the necessity in comparing the available species sensitivity distributions to the currently used assessment factors within chemical risk assessment.The presentation will provide further details on the spread of the species sensitivity distributions and the distribution of sensitivity steepnesses over all the tested chemicals will be analysed.

EFSA Scientific Opinion on the effect assessment for pesticides on sediment organisms in edge-of-field surface waters

S. Duquesne, UBA, Federal Environment agency; A. Aagaard, Pesticides Division / Danish EPA; T. Brock, Alterra, Wageningen University and Research Centre / Environmental Risk Assessment Team; B. van Hattum, Institute for Environmental Studies, VU University, de Boelelaan; M. Klein, Fraunhofer IME; I. Sundh, Swedish University of Agricultural Sciences (SLU), Department of Microbiology, Uppsala; R. Sharp, EFSA - European Food Safety Authority / Pesticides Unit; M. Egsmose, EFSA

Some aspects, proposals and/or recommendations described in the EFSA scientific opinion on the effect assessment for pesticides on sediment organisms in edge-of field surface water are presented here. They include elements of exposure as well as effect assessments since the ERA is a combination of both. The issues highlighted here are the following: Triggers for sediment ecotoxicity testing and a decision scheme based on a tiered effect assessment approach for different types of organisms; How to link regulatory acceptable concentrations (RACs) to predicted environmental concentration (PECs), using the ecotoxicologically relevant concentrations (ERCs) concept that is influenced by the choice of sediment layer depth, exposure metric and test duration; Methodology for introducing an accumulation factor to account in a conservative way for effects of multi-year applications; Assessment of impacts of bioaccumulation, biomagnification and secondary poisoning; Issues related to uncertainties of the current and/or proposed ERA approaches. The specific protection goals (SPGs) for sediment-inhabiting organisms are based, as for the aquatic organisms in edge of field waters, on two options, i.e. (1) the ecological threshold option (ETO), accepting negligible population effects only, and (2) the ecological recovery option (ERO), accepting some population-level effects if ecological recovery takes place within an acceptable time period. For several reasons, for the time being it is suggested that the ETO is the best option to provide adequate protection of benthic organisms.

254

Effects of sediment-spiked lufenuron on benthic macroinvertebrates in single-species tests and outdoor microcosms

T. Brock, Alterra, Wageningen University and Research Centre / Environmental Risk Assessment Team; D. Bas, L. Bibbe, University of Amsterdam / Institute for Biodiversity and Ecosystem Dynamics IBED; D. Belgers, M. Boerwinkel, Alterra, Wageninen UR / ERA team; S. Crum, Alterra Wageningen UR / ERA team; N. Diepens, Wageningen University; M. Kraak, M. Schoorl, A. Vonk, University of Amsterdam / Institute for Biodiversity and Ecosystem Dynamics IBED; I. Roessink, Alterra / ERA team

Sediment ecotoxicity studies were conducted with lufenuron, a hydrophobic benzoyl urea insecticide. The studies aimed to compare the concentration-response relationships for macroinvertebrates observed in an outdoor sediment-spiked microcosm experiment and those of 28-d sediment-spiked single-species toxicity tests with *Chironomus riparius*, *Hyalella azteca* and *Lumbriculus variegatus*. Twelve weeks after the construction of the microcosms mean measured exposure concentrations in the sediment were on average 87.7% measured initially. Treatment-related effects of sediment-spiked lufenuron in the microcosm experiment were observed for populations of insects and macrocrustaceans (lowest NOEC for benthic insects 0.8 µg a.s./g OC and for benthic crustaceans 8.5 µg a.s./g OC). Treatment-related increases in abundance (indirect effects) were observed for benthic oligochaete worms (lowest NOEC of 0.8 µg a.s./g OC). The 28-d sediment-spiked laboratory toxicity tests resulted in EC_{10} values of 0.49 µg a.s./g OC for *C. riparius*, 1.20 µg a.s./g OC for *H. azteca* and 211 µg a.s./g OC for *L. variegatus*. These data also explain why oligochaete worms did not suffer pronounced toxic effects in the microcosm experiment, but could increase in abundance due to the decline of sensitive benthic arthropod populations (release of competition). The chronic laboratory toxicity data mentioned above illustrate that the tier-1 effect assessment approach proposed by EFSA for benthic organisms and sediment-bound insecticides, using the lowest chronic EC_{10} value for the combination *C. riparius* and *H. azteca* and an assessment factor of 10, is protective for the insecticide lufenuron and the responses observed in the sediment-spiked microcosm test.

255

Applying the MDD concept to terrestrial NTA studies

F.M. Bakker, Mitox Consultants; S. Aldershof, bioresearch and evualuation

Natural terrestrial ecosystems such as meadows adjacent to cropped fields may be exposed to spray drift. The arthropod fauna of such ecosystems is generally abundant and species rich and comprises a broad array of eco(toxico)logical profiles. There are no models or model systems sufficiently fit to adequately predict the potential effect of exposure on the functioning of these ecosystems. For this reason experimental tests are performed, generally in natural ecosystems without prior manipulation. Because the arthropod fauna in such systems varies between locations and years there is a need to evaluate whether a selected site is appropriate for the purpose of the experiment, i.e. to derive regulatory acceptable exposure levels. This can only be done a posteriori. We apply the MDD concept derived by Brock et al. (2015)[1] for aquatic micro-/mesocosm studies to natural (i.e. unbounded) terrestrial off field systems as described in DeJong et al.[2]. Typically these experimental systems follow a replicated (n=4) plot design, with 30x30 m plots and multiple sampling methods over a period of 8 weeks following a single application event. A large number of arthropod taxa (800-1000) is assessed and typically at least 80-100 are sufficiently abundant for statistical hypothesis testing. As a consequence of inherent parametric constraints we use non-parametric tests for these analyses. Our primary objective is to test whether the criteria in the aquatic scheme can be applied to derive regulatory acceptable exposure levels for terrestrial systems as well. We use the decision scheme in Brock et al. (2015) to data obtained in a large number of off-field studies. MDD's were calculated using the technique provided by Van der Hoeven (2008)[3]. Potentially sensitive taxa were defined using empirical criteria, in particular whether a specific or related taxon was consistently affected by the reference treatment in different studies. Ecologically vulnerable taxa were defined similarly as taxa consistently affected by the reference item for four or more weeks in different studies. [1] T.C.M. Brock; M. Hammers-Wirtz; U. Hommen;T. Development of suitable experimental designs for semi-field trials with solitary bees

V. Kondagala, University of Koblenz-Landau / Institute for Environmental Sciences; M. Candolfi, Eurofins Agroscience Services Ecotox GmbH; T. Jütte, O. Klein, S. Knaebe, Eurofins Agroscience Services Ecotox GmbH / Ecotoxicology Field; T. Vollmer, Eurofins Agroscience Services Ecotox GmbH / Field Ecotoxicology

The publication of the proposed EFSA risk assessment of plant protection products for pollinators led to an increasing demand for experiments with non-*Apis* pollinators. However, no official guideline for the standardized semi-field trials exists so far. To overcome this lack of guidance, a semi field study was performed to continue our research and increase the knowledge about suitable test designs and the handling of the test organisms. The aim of this study was to implement a test system for trials under semi-field conditions with solitary wild bees. In the study the potential effects of exposure of bees and their brood to test item treated and untreated plants and the statistical evidence of validity were the focal points. During the exposure and after end of the exposure all relevant parameters were recorded. The test design is in accordance with a proposal from the ICPPR non- *Apis* working group. The semi-field study with the red mason bee *Osmia bicornis* (Hymenoptera, Megachilidae) was conducted in winter oilseed rape with 6 replicate tunnels per treatment group and contained a water treated control as well as two reference treatments applied with 100 g a.i./ha and 350 g a.i./ha dimethoate. The following end points were observed in the study: nest occupation by female individuals, flight activity, reproduction capacity by means of produced cells and cocoons and brood termination rate. Hatching success was also recorded to assess the viability of the used test specimens. The first results show clearly the possibility to perform semi-field studies with the red mason bee *Osmia bicornis* in winter oilseed rape. Dimethoate can be used as a toxic reference to show acute effects on adult wild bees. The endpoints chosen were useful for a study design and the variability was low with regard to the observed effects. The two rates of dimethoate tested showed already the maximum effect so that dimethoate can be used as a toxic reference in semi-field studies at the lower rate. Furthermore the statistical analysis showed that the test design is valid and repeatable.

257

Experimental design for semi-field trials to test brood affecting plant protection products with solitary bees

S. Knaebe, Eurofins Agroscience Services Ecotox GmbH / Ecotoxicology Field; M. Candolfi, Eurofins Agroscience Services Ecotox GmbH; L. Franke, J. Fricke, T. Jütte, O. Klein, A. Schuster, Eurofins Agroscience Services Ecotox GmbH / Ecotoxicology Field; T. Vollmer, Eurofins Agroscience Services Ecotox GmbH / Field Ecotoxicology

The newly proposed EFSA risk assessment of plant protection products for pollinators includes for the first time not only honey bees as test organisms but also non-Apis pollinators. However, there is no official guideline for standardized semi-field trials. To support a tiered risk assessment a semi-field study design was developed and performed in 2015 based on available publications and advices from an ICPPR workshop. The results of these studies make it possible to improve future designs and recommendations for the handling of the test organism can be given. The objective of this study was to develop a semi-field test design for plant protection products affecting brood of solitary wild bees. In the study the potential effects of exposure of adult bees and their brood to an insect growth regulator were examined. After the end of exposure the development of the progeny was followed until the following spring and the reproduction success was evaluated as an endpoint. The semi-field brood trial with the red mason bee *Osmia bicornis* (Hymenoptera, Megachilidae) was conducted in a *Phacelia* crop. The test design included a water treated control and two treatment groups. Each treatment group was replicated with 4 tunnels. The exposure period started at the beginning of July 2015. The treatment applied was fenoxycarb, an insect growth regulator also used as a reference substance in honey bee brood studies. Two rates were tested with150 g a.i./ha (T1) and 350 g a.i./ha (T2). The following endpoints were observed in the study: to evaluate sub-lethal effects on adult bees, the nest occupation of females and the flight activity was documented. I order to evaluate brood effects, the cell production, the cocoon production and the brood termination rate were assessed. To ensure equal starting conditions in all treatment groups the hatching success was recorded. The first results show, that it is possible to perform a semi-field brood study with the red mason bee *Osmia bicornis* in *Phacelia*. The bees can be stored until June and hatched specimens are still viable and fertile. Fenoxycarb can be used to introduce brood termination in eggs and larvae of red mason bees. The endpoints chosen are useful to evaluate effects on reproductive success and the variability between replicates was low. The lower rate of fenoxycarb showed already the maximum effect so that fenoxycarb can be used as a toxic reference in semi-field studies.

Methodological challenges for LCA of agricultural supply chains producing food, fibre and bioenergy

258

Comprehensive assessment of fruits and vegetables human health effects in a LCA context

K. Stylianou, University of Michigan - School of Public Health / Environmental Health Sciences; O. Jolliet, University of Michigan; P. Fantke, Technical University of Denmark / Quantitative Sustainability Assessment Division

Purpose: Nutritional effects from the 'use stage' of food items life cycle can have a substantial effect on human health; yet, they are often not considered in life cycle assessment (LCA). In our study we explore the case of increased fruit and vegetable consumption, a healthy dietary option – that could result in higher exposures to a wide variety of pesticides – and investigate the trade-offs between associated environmental and nutritional health effects. *Methods:* We employ the Combined Nutritional and Environmental Life Cycle Assessment (CONE-LCA) framework that evaluates and compares in parallel the environmental and nutritional effects of foods expressed in Disability Adjusted Life Years (DALYs). For the environmental health assessment we consider impact categories such as global warming and particulate matter (PM) as well as chemical exposure due to pesticide residues. Global warming and PM are assessed following a traditional LCA approach. For the pesticide residue exposure, we use publically available health impact scores derived from toxicological studies of numerous pesticide active ingredients. For the nutritional assessment we focus on the various health outcomes considered in the global burden of disease that are based on epidemiological studies. *Results and discussion:* Adding one serving of fruits or vegetables to the current average diet in Europe may lead to substantial nutritional health benefits. These nutritional benefits are slightly increased when we consider substitution scenarios in which the substituted food items are associated with negative health effects, such as red meat and trans-fat. Overall environmental health impacts associated with this addition are substantially smaller compared to nutritional benefits in each scenario, even when considering an uncertainty factor of 400 for the impacts of pesticide residues. *Conclusion:* The present study illustrates the importance of considering nutritional effects of food items in LCA. Our preliminary results suggest that nutritional health effects of food items can be substantial and comparable to environmental impacts, especially for nutritional foods such as fruits and vegetables. This approach could be used for making recommendations about sustainable diets and food choices.

Pesticides' impacts of bananas from different regions

T. Ponsioen, PRe Consultants / Consultancy; L. Golsteijn, M. Goedkoop, PRe Consultants; H. van der Waal, AgroFair Benelux bv

Most bananas sold in Europe nowadays have some sort of sustainability label. Consumers and supermarkets therefore may have the idea that the labelled bananas are produced in a sustainable way. Sustainability covers many social and environmental themes and several of these are addressed by the labels only to a certain extent. However, large amounts of pesticides are still used in conventional banana production, resulting in potential human health and ecosystem impacts. Using no xenobiotic pesticides at all as is the case for organic bananas is not an option for the large scale, because it needs very specific climatic and logistic conditions. Different climatic, soil conditions and production practices between farms result in large differences in the pesticide impact of bananas. In this study, the toxicity-related impacts of pesticides applied in banana production were calculated with the consensus model USEtox version 2.0 for three case studies: an organic farm in Peru, smallholder farms in Ecuador, and a conventional plantation in Panama. The resulting toxicity-related pesticide footprints show that the use of large quantities of myclobutanyl, chlorpyrifos and mancozeb in Panama case have the highest contribution to the human health impact profile. The use of azoxystrobin and mancozeb in this case shows the largest share on the impact profile for organisms in freshwater ecosystems. The footprint of the pesticides used in banana production from the Panama case is about 20 to 30 times larger than in the Ecuadorian case. In a sensitivity analysis, in each case, regionally specific landscape parameters were used to calculate specific factors for each of the pesticides used. This increased the score of the Panama case by about 300%, while the score of the Ecuador case did not change significantly. Default values for these parameters are provided by USEtox for several regions, among which for a region covering Central America and one covering Peru and southern Ecuador. Calculations with an alternative impact assessment model (USES-LCA) generally confirms the results with USEtox, but shows that the impact on terrestrial and marine ecosystems, which are not included in USEtox, can be significant.

260

Towards a consensual method to assess climate change impacts from bio-based systems

A. Benoist, CIRAD; C. Cornillier, FCBA

This study focused on climate change impact assessments of systems involving compartments of the biogenic carbon cycle, addressing the issue of assessing the actual impacts of biogenic carbon emissions and of variations in carbon stocks. A critical review was carried out on seven different characterisation models dealing with these environmental mechanisms, including five methods dealing with GreenHouse Gas (GHG) emissions - conventional Global Warming Potentials (GWP) from IPCC according to a carbon neutrality approach or to a full accounting approach, time-adjusted GWP, biogenic GWP and biogenic accounting factors - and two methods dealing with land occupation and/or transformation - ILCD / IPCC recommendation to account for carbon stock changes from land transformation and Müller-Wenk proposal adopted in the land use framework. These models were rated over eight criteria divided into four categories: completeness in terms of environmental mechanisms covered, scientific soundness, genericity, and easiness of use. Results showed that the currently recommended methods are conventional GWP according to a full accounting approach for the assessment of greenhouse gas emissions, and the ILCD / IPCC recommendation to account for carbon stock changes from land transformation. However, despite their good international acceptance, these methods fail to take into account the dynamic nature of the biogenic carbon cycle and new methods have then been developed for this purpose. These methods present many gaps but two were identified as promising characterisation models: time-adjusted GWP and Müller-Wenk proposal. Finally, a new method that benefits from the advantages of these two last methods is proposed. This method relies on the land use framework related to carbon sequestration potential with the time-adjusted GWP embedded to better reflect the dynamics and reversibility of the biogenic carbon cycle. It is compatible with full accounting approach for GHG emissions and temporary carbon storage valuation. It also remains sufficiently practicable.

261

Which functional unit to assess environmental impacts of dairy system intensification?

T. SALOU, INRA, UMR SAS / UMR SAS UMR SMART; C. Le Mouël, INRA Agrocampus Ouest / UMR SMART; H. van der Werf, INRA, UMR SAS / Environnement etAgronomie

Intensification of milk production, defined as increased production per hectare (ha) of land, invariably leads to increased impacts per ha, but its impacts per kg of milk are less clear. The aim of this study was to assess a range of environmental impacts of contrasting dairy systems that represent a wide diversity of management practices and intensification levels. We used the concept of the Technological Management Route (TMR), i.e. a logical set of technical options designed by farmers, to compare seven systems representing the diversity of milk production systems in France and a range of intensification levels. Life Cycle Assessment was used to estimate impacts of these systems using two functional units (FU): t of milk and ha of total (on- and off-farm) land occupied. With the area-based FU, we are looking for low-impact land-use systems. From this perspective, the organic and highland systems were most promising. With the mass-based FU, we consider productivity and impacts. From this perspective, a maize-silage based system seemed most promising, as it ranked lowest or second-lowest for six out of seven impacts. Dairy system intensification had three effects: i) all impacts increased per ha of land occupied, ii) eutrophication and land competition decreased per t of milk produced, and iii) other impacts changed little per t of milk produced. In other words, depending on the FU, the perceived environmental impacts of dairy system intensification differed radically. A mass-based FU is by far the dominant FU, and, in studies that go beyond the farm gate, the only FU used. Thus, current LCA practice is largely blind to environmental impacts of dairy system intensification, as it tends to ignore the environmental impacts of intensification revealed by the area-based FU. This is a sobering observation with paradoxical consequences, as this “blind spot” of current LCA practice may well tend to bias decision making in favour of intensive systems, which have high impacts per ha of land occupied. LCA-based decision making might thus increase the prevalence of intensive systems, which could increase overall impacts of the agricultural sector. Reconciling environmental impacts and productivity is difficult. Using only a mass-based FU, does not provide a balanced view of the impacts of intensification and could mislead decision makers in identifying promising dairy systems. We recommend the use of both mass-based and area-based FUs in LCAs of agricultural goods.

262

Environmental Impact of food consumption in EU

B. Notarnicola, G. Tassielli, P.A. Renzulli, University of Bari / Ionian Department of Law Economics and Environment; V. Castellani, European. Commission - Joint Research Centre / Institute for Environment and Sustainability; S. Sala, European Commission - Joint Research Centre / Sustainability Assessment unit

In order to comprehensively assess the impact of food consumption at EU level, a detailed product based LCA from ‘cradle to grave’, has been conducted aiming at: i) identifying the most representative food and beverage products consumed in the EU-27 via a statistical analysis of food consumption, selecting 2010 as reference year, ii) evaluating, via an LCA, the life cycle environmental impact of the average food consumption of an EU-27 citizen in one year following the ILCD recommendations for impact assessment, iii) developing a strategy for using the BoP food as baseline scenario for testing ecoinnovation options for impact reduction. The methodology developed for assessing the impacts of food consumption in EU, based on a basket of food products, includes the following steps: 1) Quantitative and qualitative analysis of the structure of the EU consumption category of nutrition – during the years 2000-2010 – including international trade and selection of a basket of representative products for the consumption category of nutrition for the year 2010. 2) Collection and development of process-based LCIs for the selected representative products. 3) Calculation of the environmental impact results, based on the results of the previous steps. 4) Quantitative and qualitative analysis of the environmental impacts of the selected nutrition basket, with conclusions and recommendations for the future. The overall results indicate that in the majority of the impact categories the most burdening consumed foods are meat products and dairy products. The agricultural phase is the most impacting lifecycle stage of the basket food, due to the contribution of agronomic and zoo-technical activities. Food processing and logistics follow in importance, due to their energy intensity and the related emissions to atmosphere, occurring during the production of heat, steam and electricity and during transport. Regarding the end of life, human excretion and wastewater treatments are posing burdens related to euthrophying substances. The impact assessment results of this study could be used as a means to provide an index for monitoring and analysis, in order to evaluate the effect of possible improvements within the life cycle stages and the different supply chains. A further step of the analysis should be to develop scenarios of eco-innovation and behavioural changes to test their effect at the EU scale and to prioritize their implementation.

Persistent and mobile contaminants in the aquatic environment: how to identify, analyse and regulate a

potential threat for drinking water resources (I)

263
Identification, analysis, removal and regulation of persistent and mobile organic chemicals in the drinking water cycle - The approach of the EU project PROMOTE
U. Berger, Helmholtz centre for environmental research - UFZ / Analytical Chemistry; H.P. Arp, Norwegian Geotechnical Institute; P. de Voogt, University of Amsterdam / IBED; H. Gallard, IC2MP UMR 7285 CNRS - University of Poitiers; T.P. Knepper, Hochschule Fresenius, University of Applied Sciences; M. Neumann, Federal Environment Agency (UBA) / Section IV Chemicals; J. Quintana, University of Santiago de Compostela; T. Reemtsma, Helmholtz Centre for Environmental Research
Surface water and groundwater are the two major sources for drinking water in Europe. Their chemical quality may be affected by human activities, among them the release of chemicals that we are producing and using. If these chemicals are poorly degradable (persistent) and polar (i.e., mobile in the aquatic environment), or if they are transformed into poorly degradable and polar compounds, then these chemicals may specifically be of concern with respect to contamination of water used for drinking water production and, eventually, for the quality of drinking water itself. We denote such compounds persistent mobile organic chemicals (PMOC). PMOC are generally substances of low molecular weight with a high portion of heteroatoms. They may even be ionic at neutral pH. These properties make PMOC extremely challenging to analyze, because they hamper enrichment from water as well as chromatography. Consequently, knowledge on the occurrence of PMOC in aquatic compartments (including source waters used for drinking water production) is very limited. It is thus questionable whether sufficient protection of drinking water resources with respect to PMOC is in place. PROMOTE (PROtecting water resources from MObile TracE chemicals) is a recently launched research project under the European Union Joint Programming Initiative "Water Challenges for a Changing World" (Water JPI). PROMOTE focuses on PMOC in environmental water cycles and in drinking water production. The objectives are to close the significant knowledge gaps with respect to (a) identification and prioritization of the PMOC of highest concern, (b) trace analytical methods for screening and quantitative determination of PMOC in water, (c) occurrence and levels of PMOC in groundwater and surface water, (d) environmental emissions and (e) clean-up strategies or transformation of PMOC in the drinking water production. Based on the expected results, PROMOTE strives to develop recommendations with respect to chemical regulation (REACH) and water quality monitoring (WFD watch list).

264
Ranking REACH registered chemicals for Persistency and Mobility: Neutral, Ionizable and Ionic Compounds
H. Arp, NGI / Environmental Engineering; S. Hale, NGI; T.N. Brown, TNB Research / Department of Chemistry
Herein we present a novel set of tools to identify which of the REACH registered compounds are most likely to be persistent, mobile organic compounds (PMOCs), and thereby capable of rapid and sustained distrubution in the environment and drinking water supplies. The REACH list was chosen not only because it provides an overview of which chemicals are currenlty in production, but their dossiers can contain experimental data related to mobility and persistency. We therefore conducted a literature search of these REACH dossiers as well as the peer-reviewed literature, and employed a sweet of quantitativ structure-activity relationships (QSARs) to assemble persisitency and mobility parameters. As many ionic compounds could not be handled by commercial QSARs, and only few had experimental data available, we developed simple QSARs that gave broad estimations on the likelyhood of persistency and mobility. Further, hydrolysis products were also assessed for the likelyhood of being a PMOC. These data and tools can be used to identify previously undetected drinking water contaminants, or for preventing them from occuring.

265
Screening of polar chemicals in water by liquid chromatography-high resolution mass spectrometry employing mixed-mode columns
R. Montes, University of Santiago de Compostela / IIAA Institute for Food Analysis and Research; J. Aguirre, X. Vidal, R. Rodil, R. Cela, J. Quintana, University of Santiago de Compostela
The popularization of liquid chromatography coupled to high resolution mass spectrometry (LC-HRMS) has permitted the exploitation of its high mass accuracy and resolution capacities for screening of a large set of organic pollutants without the need of having pure standards and chemical-classes targeted methods. To date, most LC-HRMS screening methods rely on reversed-phase LC (RPLC), which is quite limited for the detection of very polar chemicals. Hence, many very polar (organic) chemicals may have not been recognized as water pollutants of concern, yet, because the analytical methods developed so far are unable to detect them. However, these polar pollutants are highly mobile in the water cycle and can spread and even reach drinking water, if they are persistent, i.e. "persistent mobile organic pollutants" (PMOC). In this context, the research project PROMOTE (http://www.promote-water.eu/), funded by the Water JPI, aims to improve the knowledge on these PMOC in the water cycle, including improving analytical methods. Thus, the goal of this study was to improve the analytical detectability of PMOC by using mixed-mode LC (MMLC) combined to HRMS, for screening purposes. MMLC provides the combination of RP and ion-exchange functionalities, which allows the simultaneous determination of analytes with extremely different properties (i.e. ionic, basic, acidic and neutral), so it is a promising technology for analyzing very polar chemicals. To reach this objective, a group of over 40 very polar model chemicals with different acid/base functionalities was employed for exploring the retention behavior and then a suspect screening approach was employed for detecting PMOC in different water samples, with several commercial and non-commercial accurate mass libraries. Some of the detected chemicals include well-known PMOC, as acesulfame, perfluorobutanoic acid, trichloropropyl phosphate or metformin, and some newly detected PMOC. *Acknowledgements* - This work is financed by MINECO (JPIW2013-117), in the frame of the collaborative international consortium (WATERJPI2013-PROMOTE) of the Water Challenges for a Changing World Joint Programming Initiative (Water JPI) Pilot Call. We also acknowledge the support of *Xunta de Galicia* ("Consolidación" funds) and FEDER.

266
Identification of persistent and mobile contaminants impacting raw and drinking waters
D. Zahn; T. Frömel, T.P. Knepper, Hochschule Fresenius, University of Applied Sciences
Highly polar organic substances may be able to penetrate natural and artificial barriers and are thus mobile in the water cycle. If these mobile organic contaminants (MOC) are persistent (PMOC) against microbiological and chemical degradation, their removal during waste water treatment and drinking water purification may prove difficult. When these substances are present in high concentrations, toxic or undergo toxication, problems for the aquatic environment and human health may arise. As a consequence of the lack of established analytical methods for MOC, only limited information about their occurrence and origin is available, which severely exacerbates the sophisticated monitoring and effective regulation of PMOC and their precursors. To identify potential PMOC, and thus begin to close this gap in knowledge we analysed 20 water samples form five European countries, including WWTP effluents, surface waters, ground waters and drinking waters. Two independent pre-treatment methods were deployed to ensure a broad coverage of potential PMOC for a subsequent HILIC-HRMS non-target screening. As sample pre-treatment methods evaporation and reconstitution and an SPE method utilizing WAX, WCX and GCB materials in one cartridge were performed. Thus the pre-concentration of the samples and the solvent exchange necessary for the sensitive analysis of water samples with HILIC-HRMS were achieved. Detected substances were prioritized based on their signal intensities and frequency of detection, whereby substances detected in drinking water were given the highest priority. To identify high priority substances, their fragmentation behaviour was investigated and H/D exchange was performed to further facilitate identification. Once a tentative identification was achieved, the fragmentation pattern as well as the retention time were compared with a reference substance, if available. If the comparison of fragmentation patterns was inconclusive or the fragmentation of a substance yielded only few or very common fragments, the retention times of the analyte and the reference substance were compared on a second column with a complementary selectivity to increase the confidence level of identification.

267
Pyrazole, a polar new emerging industrial contaminant
E. Emke, A. Kolkman, D. Vughs, KWR Watercycle Research Institute; K.A. Baken, KWR Watercycle Research Institute / CWG; P. Bauerlein, KWR Watercycle Research Institute / Analytical and Environmental Chemistry; A. van Wezel, KWR Watercycle Research Institute / Chemical Water Quality and Health; P. de Voogt, University of Amsterdam / IBED
In the Netherlands around 40% of the drinking water originates from surface water taken mainly from the river Rhine and Meuse. Therefore several early warning monitoring stations safeguard the quality of water taken in by an array of sensors, daphnia, algae, mussels and instrumental techniques like automated HPLC Diode Array Detection (DAD). The different monitoring stations employ a common best practice protocol HPLC-DAD screening, the so-called UV fingerprint screening which is performed daily. A uniform interchangeable UV-spectrum database helps to identify unknowns without the need for a standard. Known and unknown compounds are followed by using their retention time index, their UV spectrum, and internal standard equivalents. This summer a daphnia sensor and the mussel monitor were triggered in the river Meuse. A sample was measured by the UV fingerprint screening showing a large broad peak emerging with a relative short retention index (7.62) indicating a contaminant with a highly polar nature not present in the UV database. This resulted in a closedown of the water intake for the production of drinking water. The aim of this study was to identify this new emerging compound by hyphenating the HPLC-DAD to the LTQ-FT-Orbitrap-MS. Non-target screening LCMS is most often employing electro spray ionization (ESI) as an interface but the unknown compound could not be targeted by ESI and hence the switch was made to atmospheric chemical

ionisation interface (APCI). This resulted in a clear intense corresponding signal (34 fold higher in counts than HESI) in the mass spectrometer corresponding with the exact retention time on the HPLC-DAD, but no fragmentation was observed. The structural formula was found to be $C_3H_4N_2$ and two possible suspects were selected based on structure and log K_{ow} namely imidazole and pyrazole. The latter was a perfect match and through establishing a calibration curve the concentration in the alarm sample was found to be ~100μg/l. Pyrazole is widely used as an starting product for the synthesis of pharmaceuticals and pesticides and a known industrial by-product. Now that pyrazole has been identified as an industrial contaminant in surface water, the toxic properties of the substance can be elucidated in order to establish health based guideline values for (sources of) drinking water

Threat of drinking water resources pollution in the vicinity of Novi Sad
I. Mihajlovic, Faculty of Technical Sciences University of Novi Sad; M. Vojinovic MIloradov, Faculty of Technical Sciences University of Novi Sad / Department of Environmental Engineering and Occupational Safety and Health; J. Radonic, Faculty of Technical Sciences / Department of Environmental Engineering and Occupational Safety and Health; M. Turk-Sekulic, University of Novi Sad / Department of Environmental Engineering and Occupational Safety and Health; M. Sremacki, University of Novi Sad, Faculty of Technical Sciences; I. Spanik, Slovak University of Technology in Bratislava
The available information and results about pollution of raw water used for abstraction of drinking water in Novi Sad municipality are significant for good eco-status of surface water in river Danube, risk management as wll as for protection and improvement of human health and safety. A special interest is devoted to the Danube River as an important source of drinking water in Europe and also for Novi Sad inhabitants.The main goal of the NATO project was to reduce and prevent risks related to environmental quality of surface water and related aquifers used for abstraction of drinking water. Based on the conducted three screening and two target analyses, the raw water entering water treatment plant contained approximately 100 different organic compounds. Selected compounds represent the most frequent groups that were identified, such as linear and branched alkanes, carboxylic acids, alcohols, pesticides, hormones and others. Contamination of raw water by two emerging substances 1-octanol and benzophenone which were found in almost all samples of wastewater and Danube surface water was observed. Prioritization based on occurrence and predicted toxicity data has been conducted in order to generate the list of priority substances relevant for the water-monitoring network in the city of Novi Sad. According to those results the list of 300 relevant organic and inorganic compounds was designed, which represent a potential threat for contamination of raw water used for preparation of drinking water. Obtained list served as input data for the establishment of standard operating procedure within the Novi Sad municipality and assessment of risk for relevant detected pollutants. Implementation of joint risk management plans and strategies against hazards, which might be caused by the chemical substances in surface and raw water, could serve as an example for other cities with similar drinking water production in Serbia as well as in surrounding countries. **Acknowledgement:** The research has been supported by NATO Science for Peace Project (ESP.EAP.SFP 984087) and III46009 Project.

Ecotoxicology and risk assessment of nanomaterials - Grouping and read-across

269
Preliminary outcomes of the OECD Expert Meeting on 'Grouping and read-across in hazard assessment regarding specific issues for nanomaterials'
J. Riego Sintes, K. Rasmussen, Joint Research Centre / Nanobiosciences Unit; S. Gottardo; A. Mech, Joint Research Centre / Nanobiosciences Unit; A. Worth, Joint Research Centre / Institute for Health and Consumer Protection IHCP; A. Kobe, European Commission; J. Holmqvist, European Chemicals Agency; M. González, Organization for Economic Cooperation and Development; P. Kearns, Organization for Economic Cooperation and Development / Environment Department
Manufactured Nanomaterials (MNs) are being developed in many different variations, including different sizes, shapes and surface functionalizations. While this is a positive driver for economic development and innovation, it does give rise to the need for both public regulatory authorities and industry to assess the environmental, health and/or safety concerns for all MNs that access the market. Concerns associated with a MN may be different to the one(s) for a corresponding bulk material, if existing. For those MNs there is a need to generate the data to draw the hazard profile. Whenever possible, such information should be generated by means other than vertebrate animal testing. Recently the OECD published its 'Guidance on grouping of chemicals, second edition' (2014). For MNs, it was concluded that, in addition to structural similarity, a set of physicochemical properties need to be considered for grouping and read-across. However, this issue was on purpose not further developed in the OECD Guidance due to the recognition that a better understanding of the relationships between MNs' physicochemical properties and (eco)toxicological behaviour or environmental fate is necessary before establishing accepted principles for grouping of MNs and provide recommendations on how to use existing data from bulk materials or other MNs in a read-across case. Since then, progress has been made in both regulatory and scientific communities. To discuss the most recent advancements an EU-sponsored OECD Expert Meeting on 'Grouping and read-across in hazard assessment regarding specific issues for nanomaterials' is held over two days in Brussels on 13-14 April 2016. The main focus of the OECD Expert Meeting is on producing practical, concrete recommendations on grouping and read-across for MNs for the best uptake in a regulatory context. This oral presentation will provide an overview of the state-of-the-art on grouping and read-across of MNs based on the documents and information shared at the OECD Expert Meeting as well as best practices and lessons learnt from existing case-studies. In addition, preliminary findings from the discussions in break-out sessions will be reported and discussed with the aim of outlining possible ways forward. \n

A strategy for read-across between nanoforms
E.A. Bleeker, RIVM; F. van Broekhuizen, A.G. Oomen, National Institute for Public Health and the Environment RIVM; N. Andersson, A. Kapanen, A. Sumrein, European Chemicals Agency ECHA; K. Rasmussen, J. Riego Sintes, Joint Research Centre / Nanobiosciences Unit; J. Holmqvist, European Chemicals Agency
Grouping of substances and read-across are valuable approaches in regulatory frameworks to minimise costs and animal testing. Where experimental data are insufficiently available for hazard characterisation one may in some cases predict the properties of a substance based on data from structurally similar substances. Also for nanomaterials, read-across and grouping approaches may be an important means to reduce costs of information generation and addressing data gaps. Based on existing knowledge and approaches, we developed a systematic strategy to substantiate read-across for nanoforms of the same substance with a focus on compliance with the EU REACH Regulation. The strategy comprises six different steps, including (1) identification and characterisation of the nanoform(s), (2) when possible formation of initial groups of nanoforms based on physico-chemical parameters (e.g. aspect ratio, or water solubility and dissolution rate), (3) identification of available information and data gaps for each nanoform per endpoint, (4) hypothesis driven identification of source materials to read across from, (5) where necessary additional testing to substantiate the read-across, and (6) assessing the new data and remaining uncertainties to conclude on the read-across arguments. Where read-across cannot be substantiated, the strategy foresees reiterating (some of) the steps, or performing appropriate testing to fulfil the information requirement(s) in REACH (or other regulatory framework). The presented strategy points towards the availability of data on physico-chemical parameters of each nanoform as the crucial starting point to obtain a better understanding on its (environmental) behaviour, fate, toxicokinetics and toxicity. This is the cornerstone in developing a scientific, robust justification for grouping and read-across. To improve understanding, further (international) coordination and collaboration in research is advisable. Furthermore, data quality is critical, and monitoring of physico-chemical parameters during testing is therefore a key element. This also requires harmonisation and standardisation of test methods for physico-chemical, toxicokinetics and hazard endpoints.

271
Grouping of nanomaterials regarding their fate and behaviour in the environment - first hypotheses and future work
C. Nickel, Institute of Energy and Envionmental Technology e.V. - IUTA / Air Quality Sustainable Nanotechnology; M. Herrchen, Fraunhofer IME Institute for Molecular Biology and Applied Ecology; K. Hund-Rinke, Fraunhofer IME; D. Kühnel, Helmholtz-Centre for Environmental Research / Bioanalytical Ecotoxicology; K. Schwirn, German Federal Environment Agency; T.A. Kuhlbusch, Institute of Energy and Environmental Technology e.V. - IUTA / Air Quality Sustainable Nanotechnology
A challenge of nanomaterials in products is their optimal use and at the same times the safe handling for humans and the environment along the whole life cycle. Several studies showed the release of NM and their transport to all environmental compartments. The application of the nanomaterial based product, the NM properties and the exposure pathway will affect the behaviour and fate of the NM in the environment and as a result the exposure of the environment, worker and consumer. The fate and behaviour in the environment and their concentration are important information for a thorough risk assessment. The potential risk has currently to be assessed case by case since no tested grouping or read across is available for the large varieties of NM. This case by case approach is time and cost consuming. Therefore, a grouping of NM and read across between different materials is indispensable and one mayor target for future risk assessment. The grouping of nanomaterials can be difficult as different perspectives and research areas are involved. Within nanoGRAVUR different aspects of grouping, read across and tiered approaches for release, exposure, hazard potential and risk analysis in view of all relevant protective targets, workers, consumers and environment are explored. The aim is to develop usable and practicable approaches within the framework of (pre-)regulative testing. One of the first steps is the set-up of different criterion catalogues based on literature

data. These catalogues will comprise NM relevant parameters such as physical chemical properties, the respective potentials of exposure, including release and environmental fate, hazard (eco- and human toxicity) and risk. Based on these catalogues grouping hypotheses for NM will be derived and evaluated in a second step. The presentation will focus on the grouping hypothesis for NM in view of environmental fate and behaviour. The first concept based on literature data, about NM transformation and mobility in air, water, sediments and soils. The concept and the planned experiments for verification or falsification of the hypothesis will be presented and discussed with the scientific community. We see the input by the scientific community at this early stage as very valuable to complete this approach and to increase the acceptability of the grouping concept in the end. The results are generated in framework of the project nanoGRAVUR which is founded from the German BMBF, Grant No.: 03XP0002

272
The use of NM libraries for read across estimation - Organism and gene effects in E. crypticus exposed to TiO2-Fe doped NM library
M.J. Amorim, Universidade de Aveiro / Department of Biology and CESAM; S.I. Gomes, University of Aveiro / Department of Biology CESAM; C.P. Roca, University of Aarhus / Biosciences; S. Pokhrel, Bremen University / Department of Production Engineering; F. von der Kammer, University of Vienna / Department of Environmental Geosciences; J.J. Scott-Fordsmand, Aarhus University / Biosciences
Nearly all ecotoxicological studies with nanomaterials (NMs) are focused on testing one or a few NMs. More systematic approaches to compare effects across many NMs with different but related characters/descriptors (e.g. different aspect-ratios or surface activities) are rarely available, especially in ecotoxicology. Therefore, there is an urgent need to provide tools that allow to develop an (eco)toxicological dataset containing comprehensive coverage of NP toxicity, with the aim of extrapolating acquired information across NMs. NM libraries are an excellent tool for alternative testing and modelling. In the present study a custom-designed Fe-doped TiO2 NM library was used, covering a wide spectrum of properties. Additionally, the reference TiO2 materials from JRC were tested (NM 103-5). *Enchytraeus crypticus* (Oligochateta) was used as test species since it is both environmentally relevant (as an important soil representative oligochaete and a standard species) and also a genomic model, with a high-throughput (HTP) transcriptomic library. Effects were assessed at the organism (survival, reproduction) and gene level (differential gene expression, microarray). Gene expressions were linked to population effects by using population Effect Concentrations (e.g. ca. EC50) as exposure levels. Material-specific effects were observed. The microarray study across the 11 materials showed that the profiles of DEGs varied among the materials. Analysis of gene ontology terms showed sub-clustering of the different materials, whereas the study of affected pathways provided the basis for mechanism interpretation.

273
Predicting Nanoparticle uptake into cells by easily measurable Nanoparticle properties
K. Kettler, Radboud University Nijmegen / Department of Environmental Science; D. van de Meent, RIVM / DMG; J. Hendriks, Radboud University Nijmegen / Department of Environmental Sciences
The increasing number of NP products poses increasing human health risks by particle exposure. Serious concerns about toxicological and environmental effects have been raised because in several in vitro studies adverse effects have been shown in various cell lines. Unfortunately, effects are often measured after a single fixed time point based on exposure dose, neglecting uptake kinetics and time-dependent internal cellular concentration. Two fundamental biological processes can be employed by NPs to enter cells: Endocytosis by all eukaryotic, non-phagocytic cells, and phagocytosis in specialised cells. When looking at NPs, this can be considered a so called Trojan horse effect, because cells take up the particles mistaking them for nutrients. This can result in high levels of NPs inside the cell. Various researcher show the effect of different NP properties, e.g. size and charge, on uptake into the cells. Patterns are albeit uncertain due to the lack of systematic studies and lack of determination of uptake in toxicity studies, but patterns are slowly emerging. To overcome the problem that not every of the numerous NPs can be tested in the laboratory (for uptake and/or toxicity), we aim to combine empirical studies with modelling for a cost- and time-effective risk assessment (RA). We determine uptake rate constants and elimination rate constants in dependence of NP size and charge from published experimental results. We distinguish between phagocytic and non-phagocytic cells. For non-phagocytic cells there seems to be a size optimum for uptake of 50 nm NPs based on NP numbers, smaller and larger NPs are taken up to a lesser extent. This optimum might shift when results are expressed as mass of the core material of the NPs. An increase in positive or negative surface charge leads to increased NP uptake in comparison to less or uncharged NPs. Positively charged particles are taken up more extensively compared to negatively charged NPs when the absolute zeta potential is similar. Understanding NP properties that determine their transport across cell membranes will improve our understanding of their toxicity and is crucial for RA. Predictions of NP uptake will allow to prioritize NPs for testing and to develop products that are safe-by-design. Furthermore, identification and understanding of the most important NP properties that determine NP uptake into cells is the first step towards the understanding of their accumulation along the food chain.

Amphipods as models to investigate toxicology of environmental contaminants at the land-sea interface

274
Application of a multiplexed quantitation of protein biomarkers in the invertebrate species Gammarus fossarum: interest to environmental monitoring
D.D. Gouveia, Irstea Lyon / UR MALY Laboratoire Ecotoxicologie; A. Charnot, UMR; A. Salvodor, ISA - Université Lyon 1; C. Almunia, CEA; J. Armengaud, CEA / Laboratoire de Biochimie des Systemes Perturbés; a. chaumot, O. Geffard, Irstea / UR MALY Laboratoire Ecotoxicologie
Sub-organismal information provided by the measurement of molecular biomarkers is a relevant approach for environmental biomonitoring (e.g. OSPAR marine strategy). Changes in molecular biomarkers can be related to an exposure to chemical compounds and some of them provide early warning indicators of possible effects on the ecosystem. However, the routine use of these tools in biomonitoring is confronted with several limitations, specifically in invertebrates. The most relevant limitations consist of the lack of specific quantification methods for each species, and the fact that each biomarker measurement involves a specific method, leading to very expensive biomonitoring strategies in time, cost and biological samples. Recently, an approach called “proteogenomics” emerged as a relevant strategy for the discovery of proteins in non-model organisms. With this approach, our consortium created a database consisting of 1873 experimentally validated proteins of the amphipod crustacean *Gammarus fossarum*, a sentinel species for continental water biomonitoring. Using this protein database, the objective of the present study was to setup an innovative approach to permit fast and specific identification and simultaneous quantification of proteins of interest in this invertebrate species. We applied a mass spectrometry based multiplexed quantitation methodology (Selected Reaction Monitoring – SRM) to study 55 proteins of interest. Identification of specific proteotypic peptides, physiological monitoring of associated proteins and their interest as biomarkers in *G. fossarum* were assessed by studying their change through male and female reproductive cycles, during food privation or after exposure to contamination (model compounds in the laboratory and *in situ* caging). This novel approach for multi-marker quantification was successfully applied for ecotoxicological analysis in an invertebrate species known for its relevance in environmental monitoring. The concentrations of several biomarkers of interest were simultaneously monitored during the physiological processes and their sensitivity to toxic contamination was demonstrated, showing the relevance of this innovative analytical approach for invertebrate ecotoxicology. In addition, we applied the measurement of molecular biomarkers for environmental biomonitoring. This breakthrough methodology in ecotoxicology constitutes a valid alternative to the time-consuming, biomarker-specific strategies currently used.

275
Bioconcentration and biotransformation of selected pharmaceuticals in the freshwater amphipod, Gammarus pulex
T.H. Miller, G. McEneff, Kings College London / Analytical and Environmental Sciences; L. Stott, N. Bury, Kings College London / Division of Diabetes and Nutritional Sciences; S. Owen, AstraZeneca / Safety Health Environment; L. Barron, Kings College London / Analytical and Environmental Science
The aquatic environment is continually exposed to contaminants via wastewater treatment plant effluents. These compounds may have adverse effects on reproduction, development and behaviour in biota.[1] A previous investigation has shown occurrence of several pharmaceuticals in the freshwater amphipod *G. pulex*.[2] However, the potential for these xenobiotics to accumulate is not well understood. Herein, the uptake and elimination kinetics of selected pharmaceuticals in *G. pulex* is presented using both liquid scintillation counting (LSC) and liquid chromatography-tandem mass spectrometry (LC-MS/MS). Gammarids were exposed to 16 pharmaceuticals covering classes of antibiotics, anticonvulsants, non-steroidal anti-inflammatories (NSAIDs), histamine H_2 receptor antagonists, beta-adrenergic agonists and beta-blockers individually for 96 h with a 48 h uptake and depuration phase, respectively. Analysis was performed using either LSC or LC-MS/MS in positive and negative electrospray ionisation modes. Uptake and elimination kinetics were determined and bioconcentration factors (BCFs) subsequently estimated. Both methods of analysis were in good agreement and overall the bioconcentration of these pharmaceuticals remained low with BCFs ranging from 12 - 212. Different methods of modelling used to estimate the kinetic BCFs showed large variation which was attributed to a decreasing trend observed in the uptake rate constant (k_1). Furthermore the LC-MS/MS method allowed the confirmatory identification and quantification of several biotransformation products resulting from exposures to propranolol, carbamazepine and diazepam. The biotransformation indicates that these organisms are capable of Phase 1 and 2 metabolism, supporting potential further use as a replacement of fish models. Finally, the results suggested that the

bioconcentration potential of these pharmaceuticals is relatively low. References. 1) Daughton, C.G. & Ternes, T.A. (1999). *Environ. Health. Persp.*, 107(6), 907-938. 2) Miller, T.H., et al. (2015). *Sci. Total. Environ.,* 511: 153-160.

276

Seasonal sensitivity of Gammarus pulex towards cypermethrin

K. Dalhoff, University of Copenhagen / Department of Plant and Environmental Sciences; J.J. Rasmussen, Aarhus University / bioscience; N. Cedergreen, University of Copenhagen / Plant and Environmental Sciences

One of the most commonly used classes of pesticides in Danish agriculture is the synthetic pyrethroids which constitute approximately 90 percent of the total insecticide usage. The pyrethroids can enter surface waters by spray drift, colloid facilitated transport or leaching through tile drains and even short pulses of pyrethroids have been shown to be highly toxic to different aquatic invertebrates with EC_{50}-values in the ng L^{-1} range. The purpose of the current study was to investigate the variance in seasonal sensitivity of the freshwater invertebrate *Gammarus pulex* towards a short (90 minutes) pulse of the pyrethroid insecticide cypermethrin. We hypothesise that the gammarids are most sensitive during spring and the least sensitive during fall due to the general increase in fitness during summer and fall such as formation of fatty acids and proteins. To test the hypothesis, gammarids were collected in a local stream, acclimated for three days and subsequently exposed to a 90 minute pulse of cypermethrin before being transferred to clean medium for recovery, where immobilization and death were followed for seven days. To get an indication of the fitness levels of the exposed gammarids the composition of fatty acids, protein content and *in vitro* cytochrome P450 (ECOD) activity were measured in non-exposed gammarids collected at the same dates as the exposed gammarids. The results of the preliminary test period of February through October seem to support our hypothesis as the estimated EC_{50}-values were lowest during spring and early summer with the exception of March and May. The seven days EC_{50}-estimates varied from 0.29 ± 0.06 to 1.94 ± 0.60 $\mu g\ L^{-1}$ with the lowest estimate observed in April and the highest in October, respectively. This several fold difference in pyrethroid sensitivity may be explained by different fitness levels of the collected gammarids. Fitness levels measured as their lipid and protein content, are expected to increase during fall due to the increase in food sources caused by the leaf-fall. An increased protein level may very well result in a higher level of cytochrome P450 activity, which potentially can explain the decrease in sensitivity during fall, whereas an increase in lipid content might increase the proportion of cypermethrin being contained in an inactive form in the lipid fraction.

277

Silver absorption kinetics in hemolymph of the marine amphipod (Parhyale hawaiensis) exposed via water

M. Vannuci-Silva, S. Cadore, UNICAMP; G. Umbuzeiro, SCHOOL OF TECHNOLOGY -UNICAMP / LEAL

Nowadays, silver's release into the environment is becoming an environmental concern, due, specially, to its large incorporation in nanomaterials. Absorption kinetics studies can be helpful to elucidate the toxicity mechanism of those contaminants. Therefore, the determination of silver concentration in the hemolymph of exposed organisms can be an interesting exposure measurement but, because of the relatively small size of these organisms, this task is quite challenging. The aim of this study was to evaluate the silver absorption kinetics in organism exposed to silver nitrate via water. As a next step, organisms exposed to silver nanoparticles will be studied. Experiments were performed using adult organisms of *Parhyale hawaiensis* (8 months) individually exposed. The Ag concentrations of exposure were 0; 5; 10; 25; 50 and 100 $\mu g\ L^{-1}$ prepared with $AgNO_3$ and reconstituted saline water (salinity 30). The exposure times were: 14, 24, 48, 72 and 96 hours. After exposure, hemolymph (approximately 0.5 μL per organism) was collected and weighted. Three pooled samples of 4 organisms were tested per exposure concentration and per time. The pooled hemolymph was diluted in 1 mL of HNO_3 0.05%. Copper concentration in the hemolymph was also determined and used as a possible internal standard because this metal can be found in hemocyanin. An Agilent 7700x Inductively Coupled Plasma Mass Spectroscopy was used for Ag and Cu determinations. The limits of detection for Ag and Cu were 0.043 and 0.027 $\mu g\ L^{-1}$, respectively. Silver concentrations in the hemolymph increased with the increase of Ag in water and with higher exposure times, reaching 14 ng mg^{-1}. Silver seems to be regulated by either Ag uptake inhibition or actively excretion in those organisms, especially when the ion concentration is higher than 50 $\mu g\ L^{-1}$ in the water, regardless the time of exposure. Copper concentrations remained from 60 to 120 ng mg^{-1}, regardless of variation in silver concentration in the water. The observed variation is probably due to the physiological state of the organisms such as molting stages, but additional studies are required to verify the adequacy of this measurement as an internal standard. The measurement of metals in hemolymph of such small organisms can be an interesting tool and it will be applied in silver nanoparticles toxicity studies.

278

Effects of low dose radiation on reproduction and behaviour of the amphipod, Echinogammarus marinus

N. Fuller, University of Portsmouth / Biology; J.T. Smith, University of Portsmouth / School of Earth and Environmental Sciences; S.A. Kohler, A. Ford, University of Portsmouth / Biological Sciences

Impacts of environmentally relevant doses of ionising radiation on aquatic biota are poorly understood. Significant data gaps for a range of organisms coupled with high profile nuclear incidents such as Chernobyl and Fukushima have driven a re-examination of the impacts of radionuclides. *Echinogammarus marinus* is a widespread intertidal amphipod which has gained prominence as a model species in both ecological and ecotoxicological studies. The aims of the present study were: 1) to develop a method for ecotoxicity testing of contaminants on the reproduction of model amphipods;2) To investigate the impact of chronic, low-dose ionising radiation exposure on the quantity and quality of spermatozoa in *E.marinus*;3) To elucidate the impact of radionuclides on crustacean behaviour patterns. *E. marinus* were exposed to beta radiation (phosphorous 32; P32) at a range of activity concentrations from 0 to 69 Bq/mL. Mean dose rates over the 14 day exposure period of 0.2, 1 and 9 mGy/d^{-1} were calculated. Subsequently, behavioural assays were performed using video tracking software (Ethovision XT) over an 8 minute alternating light/dark cycle. Sperm quantity and quality were ascertained using dissection and fluorescent (LIVE/DEAD) staining techniques. Following light stimulation, a significant reduction in swimming velocity was observed during dark phases of the assay at all dose rates. Exposure to P32 resulted in a decrease in sperm viability across all dose rates compared to the control although this was only significant in the 1 mGy/d^{-1} exposure group (~11% reduction). No significant differences in total spermatozoa numbers were recorded in any of the treatments. This study has developed sensitive biomarkers highlighting possible impacts of sperm quality but not quantity. A number of studies have suggested that a reduction in sperm quality may be detrimental to crustacean species at higher levels of organisation therefore ongoing research will aim to determine the presence of DNA damage and the knock-on effects on fertilisation success. These preliminary findings indicate that ionising radiation has the potential to alter male fertility and behavioural patterns at dose rates below those encountered in radioactively contaminated environments. Such studies will improve our understanding of the impacts of large scale nuclear incidents such as Chernobyl and Fukushima.

Discussion

G. Umbuzeiro, SCHOOL OF TECHNOLOGY -UNICAMP / LEAL

Recent Developments and Current Issues in Bioaccumulation Assessment

280

First insight into bioconcentration of Ionic Liquids - an in vitro approach

J. Maszkowska, University of Bremen / Center for Environmental Research and Sustainable Technology; P. Stepnowski, University of Gdansk / Department of Environmental Analysis; J. Thoeming, M. Markiewicz, S. Stolte, University of Bremen / Center for Environmental Research and Sustainable Technology

Thousands of different Ionic Liquids (ILs) have been synthesized and few hundreds are commercially available. ILs are used nowadays from small-scale through pilot plant to large-scale industrial applications. This comes with the increased probability that they will be continuously released into the biosphere, for example, as process effluents or consumer products, or in larger amounts as accidental spills. Hence they should be considered as potential pollutants (PPs). Bioaccumulation is of the highest concern for environmental risk assessment of chemicals, since it is known to cause far-reaching hazards to wildlife and human health. Generally, the experimental measurement of bioaccumulation is time-consuming, expensive, and due to ethical concerns regarding animal welfare not feasible for large sets of chemicals. Thus prediction models - mainly based on easily determinable physicochemical properties such as the octanol-water partition coefficient - are usually used. However the existing prediction models often give inappropriate and inaccurate results for ionogenic compounds and permanently charged organic chemicals. This is due to the fact that classical bioaccumulation models neither sufficiently consider ion–macromolecule interactions nor interactions of cations and anions in solution - both strongly influencing the transport, uptake and bioavailability of ions. Therefore the main aim of this study was to understand the interactions of organic ions, and ion pairs in particular, with *in vitro* biological systems and their consequences in terms of bioconcentration. On the basis of obtained results strong evidence for the influence of alkyl chain length and thus hydrophobicity was presented. Moreover the influence of hydrophobic counterion on lipid membrane partitioning was determined. The study also showed that lipid membrane partitioning of ILs is concentration – dependent. Hydrophobic ILs had rather high affinity to lipid membranes suggesting significant bioconcentration potential. Since hydrophobic counterion clearly exhibited membrane partitioning of IL cation, influence of co-contaminants on bioconcentration potential should be always considered. *Acknowledgement This research has been supported by the Institutional Strategy of the University of Bremen, funded by the German Excellence Initiative.*

281
Improving fish bioaccumulation assessment for ionogenic compounds by in vitro measurements of the liver S9 clearance rates
s. droge, Utrecht University / IRAS; Y. Chen, Ctgb; J. Hermens, Utrecht University / Institute for Risk Assessment Sciences
Under the chemical legislation REACH, adequate estimates of the bioaccumulation potential of thousands of chemicals, of which 50 % is ionogenic, are required. Only recently, a bioconcentration model specifically for ionogenic organic chemicals (BIONIC) in fish has been developed. Bioaccumulation data on ionogenic organic chemicals (IOCs) are scarce, but also the QSARs used to parameterize the critical uptake rate constant, tissue distribution and biotransformation rates are poorly validated for IOCs. The available *in vivo* fish biotransformation rates for IOCs do not cover many fully ionized structures, and also do not equally cover all different types of acids (phenolates, carboxylates, sulfonates, sulfates) and types of bases (primary, secondary, and tertiary amines, and quaternary ammonium salts). We used a straightforward *in vitro* biotransformation assay with a single batch of S9 Rainbow trout liver homogenate (Rt-S9) in order to derive consistent measurements of intrinsic hepatic clearance rates ($CL_{in\ vitro,intr}$)on 50 IOCs, covering nearly all monoprotic IOC types. Since the Rt-S9 is well characterized and standardized and includes both phase I and phase II enzymatic conversions, this data set covers the baseline ability of uninduced fish to biotransform xenobiotic ionic compounds in an environmental exposure, which would be a valuable conservative approach. The next challenge is to extrapolate these values to whole organism transformation rates, after which they can be applied to the BIONIC model. The 50 IOCs include many simple chemical structures that allow for a careful evaluation of the influence on $CL_{in\ vitro,intr}$ of (A) the ionizable group, (B) the hydrophobicity (non-polar moieties) of IOC structures, (C) the position of the charged group in the IOC (interior or exterior of the structure), (D) branching (related to C), and (E) to some extent specific polar functional groups. This data set on IOCs pose an important shortcut to current uncertainties in deriving biotransformation rates from in vivo measurements for IOCs, and could present a framework to establish a more extensive Rt-S9 QSAR that specifically addresses all kinds of ionizable contaminants. The *in vitro* Rt-S9 data can further be used to evaluate and support the BIONIC bioaccumulation model k_{MET}-QSARs that are based on *in vivo* data.

282
Identifying obstacles to the application of the one concentration approach for fish bioconcentration testing
N. Burden, NC3Rs; S.K. Maynard, Syngenta / Environmental Safety; L. Weltje, BASF SE / Crop Protection Ecotoxicology; J. Wheeler, Dow Agrosciences
Fish bioconcentration studies assist in determining the potential for substances to bioaccumulate. The resulting bioconcentration factor (BCF) value is used as part of Persistence, Bioaccumulation and Toxicity (PBT) and secondary poisoning assessments. International data requirements for general chemicals and plant protection products (PPPs) include triggers for determining BCF values, generally where bioconcentration might be expected. Bioconcentration tests are time consuming, expensive, and use a minimum of 108 animals per study. Alternative methods that replace, reduce or refine the use of fish for BCF testing would therefore be of value in improving efficiency, reducing costs and supporting animal welfare considerations. The 2012 revision of the OECD Test Guideline for BCF testing (TG 305) provides the option to use only one exposure concentration, when justification is provided, although two exposure concentrations may still be required for some regulatory purposes. Recently this justification has been demonstrated for general chemicals and PPPs, where it was shown that one concentration can be tested without compromising the BCF determination. This provides a strong data-driven rationale for using the one test concentration approach for BCF assessment of general chemicals and PPP active substances, and where applied would reduce the number of fish used for this purpose by one third. In 2015 we conducted a survey across academia, regulatory bodies and industry to determine how often the one concentration approach is being applied in practice, and identify the barriers to its widespread uptake. Fifty-eight participants from Asia (n=3), Europe (n=21), North America (n=30), and Latin America (n=4) completed the survey. Of these, 31 respondents were scientists from organisations which conduct fish bioconcentration testing for regulatory purposes, of which 29 responded to the question 'How often does your company apply the one concentration approach in practice?'. The majority of these scientists (48%) occasionally apply the approach, with 41% never utilising the approach, and only 10% using it routinely. Twenty-two of these scientists identified barriers to its uptake. These were cited as a lack of global regulatory acceptance (64%), followed by scientific concerns (32%), and inertia (4%). In this presentation we will explore the barriers in more detail and discuss potential strategies to enable greater use of the one concentration approach in practice.

283
Study of biomagnification of poly- and perfluoroalkyl substances on fresh water food webs
C. Simonnet-Laprade, UMR5805 EPOC; M. Lauzent, LPTC-EPOC, University of Bordeaux / UMR EPOC LPTC; G. Munoz, Universite de Montreal / UMR EPOC LPTC; K. Le Menach, University of Bordeaux / UMR EPOC LPTC; P. Labadie, CNRS; B. Ferrari, Ecotox Centre CH; M.P. Babut, Irstea / Water; H. Budzinski, University of Bordeaux / UMR EPOC LPTC
Poly- and perfluoroalkyl substances (PFAS) are surfactants that have been synthetized and used in a wide variety of applications since the 1950s. As a consequence, PFAS are introduced via multiple pathways in the environment and some of these compounds have been detected in all compartments including aquatic systems. Even if PFAS concentrations are rarely superior to µg/L in surface waters, elevated concentrations have been reported in aquatic organisms (up to mg/kg) demonstrating their bioaccumulative properties. Recent works highlighted the importance of the use of metrics such as the Trophic Magnification Factor (describing the behavior of a compound along a food web) for bioaccumulative assessment of persistent organic pollutants. In this study, the biomagnification potential (TMF) of 23 PFAS was investigated in freshwater riverine food webs, for the first time. Thus, various biota species including fish (barbels *Barbus barbus* and chubs *Squalius cephalus*) and invertebrates representing different trophic levels (primary consumers, omnivores, herbivores, carnivores or filter feeders) were collected across 4 sites in the Rhône basin and 1 site in the Loire Basin (Eastern France). Analysis of stable isotopic ratios ($\delta^{15}N$ and $\delta^{13}C$) allowed for the determination of trophic levels (TL). Several regression approaches were compared for TMF calculation, including a classical regression, and regressions taking into account sample heterogeneity and/or left-censored values. At each site, particular care was devoted to the choice of the organism at the baseline of the food web. Fish were consistently at the top of the food chain (TL = 3-4.5) and were significantly more contaminated than invertebrates (ΣPFAS = 6–2321 *Vs* 0.8–205 $ng.g^{-1}$ ww). The most frequently detected PFAS were long-chain carboxylates and sulfonates, while shorter chain PFAS were never detected. TMFs ranged between 1.5 and 6 for long-chain PFAS, strongly suggesting their biomagnification potential in the riverine food webs investigated. TMFs could vary substantially among sites, and according to the regression model used.

284
Measuring Trophic Magnification Factors: Role of Spatial Concentration Gradients, Disequilibria and Field Sampling Design
F. Gobas, Simon Fraser University / School of Resource and Environmental Management Faculty of Environment; J. Kim, Dow Corning Corporation / Health and Environmental Sciences; J.A. Arnot, ARC Arnot Research & Consulting / Department of Physical Environmental Science; D.E. Powell, Dow Corning Corporation / Environmental Sciences; R.M. Seston, Dow Corning Corporation / Health and Environmental Sciences; K.B. Woodburn, Dow Corning Corporation / HES
Trophic magnification factors (TMFs) are field based measurements of the bioaccumulation behavior of chemicals in food-webs. TMFs can provide valuable insights into the bioaccumulation behavior of chemicals. However, like other bioaccumulation metrics, TMFs are subject to considerable uncertainty and the influence of numerous confounding variables. This study seeks to investigate the role of spatially-variable concentrations in water and sediments on the determination of the TMF. For this purpose, a multi-box food-web bioaccumulation model was developed to account for horizontal and vertical spatial concentration gradients and species movement on chemical concentrations in aquatic biota of food-webs and TMFs. Model testing through a comparison of model calculated and observed TMFs for persistent PCB congeners and biotransformable phthalate esters in a marine aquatic food-web (subject to spatial variations in chemical concentrations in water and sediments) showed good agreement between model calculated and observed TMFs. Model testing showed no systematic bias and good precision in the estimation of the TMF for PCB congeners but an apparent underestimation of the TMFs for phthalate esters. A model sensitivity analysis showed that species sampling designs that ignore the presence of concentration gradients can misidentify the TMF. The determination of the TMF is most sensitive to concentration gradients and species migration patterns for substances that are subject to a low degree of biomagnification or trophic dilution (i.e., TMFs around 1). TMFs were found to follow a strong relationship with log KOW and to be sensitive to biotransformation rates. Model calculations indicate that systems with relatively homogeneous exposure are best suited to determine TMFs that are representative of chemical bioaccumulative properties. The model is useful in anticipating the effect of spatial concentration gradients on the determination of the TMF; guiding species collection strategies in TMF studies; and interpreting the results of field bioaccumulation studies in study locations that are subject to spatial differences in chemical concentration.

285
A bioaccumulation assessment using a weight of evidence approach and Triclosan as an example
S. Pawlowski, BASF SE; J. Arnot, ARC Arnot Research & Consulting Inc.; S. Champ, BASF SE
The assessment of the bioaccumulation potential of a substance according to current regulation requirements such as REACh is based on the logKow (screening) for the first instance, followed by a fish bioconcentration factor (BCF) study following OECD 305 test guidelines for the final assessment. The

standardized fish BCF study results are usually considered definitive for the "B" assessment and the potential for accumulation along the food chain (secondary poisoning). Normalized to a 5% lipid content and corrected for growth, this value is considered as representative for aquatic species (i.e. fish). However, in some cases where BCF values from several tests are avialable, these values can be highly variable indicating an uncertainty among those data. For example, in case of Triclosan, an antimicrobial active substance, at least three guideline fish BCF studies are available revealing BCF values from about 100 to about 8700 L/kg. Other "B" metrics such as biomagnification factors (BMFs) and trophic magnification factors (TMFs) and toxicokinetic information such as the total elimination half-life (t1/2) can also be considered as lines of evidence in a weight of evidence approach for "B" assessment to address uncertainty in measured BCFs and to more fully characterize the bioaccumulative properties of a chemical. Taking all of these lines of evidence into account, it can be concluded that Triclosan does not exceed the commonly used BCF bioaccumulation criteria (thresholds). Furthermore, models parameterized with the available data calculate biomagnification factors that are less than 1; Triclosan does not biomagnify in food chains.

Environmental risk assessment of chemical mixtures: the steps ahead (II)

286
Mixture toxicity assessment using tissue concentrations - experiences from analysing real-world monitoring data
T. Backhaus, University of Gothenburg / Department of Biological and Environmental Sciences; D. Yngsell, University of Gothenburg / Department of Biological and Environmental Science; M. Gustavsson, University of Gothenburg
Norway has been monitoring populations of cod and trout since 1998 for the presence of organic contaminants including classic POPs from the "dirty dozen" such as PCBs, polychlorinated dibenzo-p-dioxins and -dibenzofurans, but also more "modern" pollutants such as flame retardants, alkylphenols, triclosan and perfluorinated compounds. Aim of the presented study was to assess whether the joint body burden of Norwegian cod and trout populations indicate an impairment of fish population health. Two sets of monitoring data were made available by the Norwegian Environment Agency for this purpose: (i) data on the pollution burden of trout populations monitored between 2010 and 2014, (ii) data collected between 1998-2013 for cod populations. In total the body burden of 151 organic compounds was monitored.\nFor each compound estimates were collected on bioaccumulation (BAF) and chronic toxicity to fish (QSAR estimates, experimental data, PNEC and EQS values). These were then combined with the biomonitoring data in order to estimate the overall risk of the exposed fish populations using Concentration Addition. For this purpose all aquatic concentrations were first re-calculated to internal body burdens by multiplying each aqueous concentration with the corresponding bioaccumulation factor. Results indicate that final risk quotients are well below one for the majority of cases, although the analysis pipeline is fraught with substantial uncertainties. In particular (i) there is a paucity of reliable toxicity data for a majority of the compounds, (ii) the application domain of existing QSAR and bioaccumulation models is too restricted to encompass highly lipophilic compounds such as e.g. several of the brominated flame retardants that were commonly found pollutants.\n\n

287
Hierarchical Bayesian approach to reduce uncertainty in the aquatic effect assessment of realistic chemical mixtures
R. Oldenkamp, Radboud University Nijmegen / Department of Environmental Science; H.W. Hendriks, Radboud University / Department of Applied Stochastics; D. van de Meent, RIVM / DMG; A.M. Ragas, Radbound University / Department of Environmental Science
Species in the aquatic environment differ in their toxicological sensitivity to the various chemicals they encounter. In aquatic risk assessment, this interspecies variation is often quantified via species sensitivity distributions. Because the information available for the characterization of these distributions is typically limited, optimal use of information is essential to reduce uncertainty involved in the assessment. Here, we show that the credibility intervals on the estimated potentially affected fraction of species after exposure to a mixture of chemicals at environmentally relevant surface water concentrations can be extremely wide if a classical approach is followed, in which each chemical in the mixture is considered in isolation. As an alternative, we propose a hierarchical Bayesian approach, in which knowledge on the toxicity of chemicals other than those assessed is incorporated. A case study with a mixture of 13 pharmaceuticals demonstrates that this hierarchical approach results in more realistic estimations of the potentially affected fraction, as a result of reduced uncertainty in species sensitivity distributions for data-poor chemicals.

288
Evaluation of pesticides monitoring programmes using a process based mixture model
J. Baas, Centre for Ecology & Hydrology; M.G. Vijver, CML Leiden University; J. Rambohul, M. Dunbar, Environment Agency England and Wales; M. van 't Zelfde, CML Leiden University; D. Spurgeon, Centre for Ecology & Hydrology; C. Svendsen, CEH, Wallingford / Pollution and Ecotoxicology
A number of European countries run large scale pesticide monitoring schemes aimed at identifying and evaluating the presence of pesticides in the environment. We compared data from a regional monitoring programme in the UK with the country wide monitoring programme in the Netherlands. In total over 15,000 samples containing over 1 million individual measurements were evaluated for effects, using a process-based mixture model that relates observed concentrations to effects on the survival probability of *Daphnia magna*. The monitoring data were analysed for effects, including and excluding below detection limit results. It showed that there are only a small number of places where we can expect to have effects on daphnids, based on measured concentrations. However, the most polluted samples would cause extinction of a daphnid population within only 30 hrs. If below detection limit measurements are included in the analysis (like the Water Framework Directive prescribes), in up to 35% of the Dutch samples the effect of the simultaneous exposure to all pesticides is such that a direct threat to the survival of daphnids exists. Our analysis also showed that detection limits in the monitoring programmes are basically too high to exclude additive mixture effects and so to make a statement on whether or not the environment is actually protected. To improve on this predictive mixture modelling can be used in combination with a more focussed monitoring programme.

289
Thresholds for synergy: How to define at what concentration a synergist stops acting as a synergist
N. Cedergreen, University of Copenhagen / Plant and Environmental Sciences; E. Becerra, D.S. Paludan, K. Dalhoff, M.A. Bjergager, University of Copenhagen / Department of Plant and Environmental Sciences
Synergy has long been a topic of concern in cummulative risk assessment. If toxicants act as synergists, they might enhance the effect of other chemicals beyond what is predicted with mixture models, which assume no interactions between chemicals. Tests for synergistic interactions are, however, most often performed with concentrations of the synergists being much higher than the concentrations occuring under natural conditions. It is likely that there is a lower threshold concentration below which the action of the synergist is neglible. The aim of this study was therefore to explore different ways of determining lower thresholds for synergistic interactions, using the known synergistic fungicides prochloraz and propiconazole together with the pyrethroid insecticide alpha-cypermethrin. Different setups and statistical methodologies were tested and lower thresholds for synergy on survival was determined for the two azole fungicides in combination with alpha-cypermethrin for the aquatic macroinvertebrates *Daphnia magna, Chironomous riparius, Gammerus Pulex and Hyallella azteca*. Synergy was defined as happening in mixtures where either EC_{50} values decreased more than two-fold below what was predicted by concentration addition (horizontal assessment) or as mixtures where the frequency of immobile animals increased more than two-fold above what was predicted by independent action (vertical assessment). Finally, survival over time was evaluated using a GUTS TKTD model letting the elimination rate constant, k_e, depend on the azole concentration. Horizontally assessed thresholds were 1.2-4.7-fold lower than vertically assessed thresholds for *D. magna*. By evaluating the effect of time, the vertical threshold was found to decrease with increasing test duration from 0.026±0.013 μM and 0.425±0.089 μM for prochloraz and propiconazole in the 48h standard tests, to 0.015±0.004 μM and 0.145±0.025 μM, in the 14-days tests on *D. magna*. The threshold concentrations for the three other species were within an order of magnitude of the *D. magna* thresholds. The GUTS modelling showed a strong decrease of k_e with increasing azole concentration, indicating that effects on k_e might also be used for setting thresholds for synergy.

290
Combined toxicity considerations in a constituents-based environmental risk assessment of multi-metallic substances
K. Oorts, F. Iaccino, ARCHE; V. VEROUGSTRAETE, Eurometaux / EHS; H. Waeterschoot, Eurometaux
There is a clear need to include a generic approach to address combined toxicity when assessing multi-metallic substances such as inorganic UVCBs, for which the assumption was made that the toxicity is driven by the toxicity of their constituents, resulting in parallel risk assessments of the constituents. Upon ECHA's request REACH registrants of inorganic UVCB intermediates committed to improve the combined toxicity assessment in their registration dossiers. However, an appropriate standard approach to address combined toxicity of metals in a regulatory framework is still missing: most standard approaches yield indeed over-conservative results such as risk scenarios at background concentrations when several metals are combined. Numerous research efforts have been performed during the last years in the field of combined toxicity of metals in the environment. This research is usually focussing on high effect concentrations, specific combinations of up to maximally 4 metals and on few standard test organisms, and restricted to well studied metals, such as Cu, Zn, Cd and Ni, with well characterised ecotoxicological effects to organisms in the water, sediment

and soil compartments. However, multi-metallic substances like the inorganic UVCBs can contain more than 10 constituents, including 'data poor' metals such as As, Pd and Te. No clear conclusions have yet been formulated on a generic approach, i.e. extrapolated to any combination of metals and to all organisms within an environmental compartment. A one day workshop was therefore organised in October 2015 with participants from academia, regulatory bodies and industry. The aim of this workshop was to bridge the gap between the scientific developments and current regulatory requirements on combined toxicity of metals. This workshop resulted in a proposal for a generic tiered approach, starting from the standard concentration addition evaluation based on summation of the PEC/PNEC ratios of the individual constituents. Several options for refinements of this standard approach, e.g. taking into account bioavailability, using msPAF calculations or assessment per trophic levels, are proposed in higher tiers, as well as screening approaches for evaluating the relative importance of the data poor constituents. This tiered approach is being tested for some case studies. In addition, several open research questions were identified for future improvement of the combined toxicity assessment of metals.

Expanding LCA: looking at organizations and at new policies

291
The EU Organisation Environmental Footprint Sector Rules (OEFSR) for the retailer sector
S. Humbert, Quantis
The European Commission started a pilot to create a "Single Market for Green Products", that aims at facilitating better information on the environmental performance of products and organisations. 26 pilots made of companies, industrial and stakeholder organisations are drafting respectively 24 Product Environmental Footprint Category Rules (PEFCR) and 2 Organisation Environmental Footprint Sector Rules (OEFSR). One of the pilot is drafting the OEFSR for the retail sector and is composed by retailers (Carrefour, Colruy, Decathlon, Picard, Kering, Office Depot), public agencies (EAA from Austria, ADEME from France and ENEA from Italy), one NGO (Global 2000), one association (PERIFEM) and one LCA consultant (Quantis). As of November 2015 an assessment of the impacts of an average retailer has been performed using the 15 impact categories required. A first OEFSR has been drafted, submitted for public consultation and accepted by the Steering Committee. The results of the assessment, the draft and its main methodological points (e.g., for direct, as well as upstream and downstream indirect contributions), as well as the benefits of this OEFSR for companies will be presented highlighting latest developments and feedback, including from the supporting studies. These points also include the issue pertaining to consistency with the product approach for a sector as interdisciplinary as the retail sector. As an example of results, an average general retailer supplying products for 3'000'000 people can have a carbon footprint in the order of magnitude of 10'000'000 t CO2-eq per year, most of it being associated with the life cycle of its products sold. Interaction between OEFSRs and PEFCRs such as cross cutting issues and consistency will also be addressed. As an example of methodological agreement that has been reached among sectors is how allocation among meat, milk, pet food and leather should be performed among cattle co-products. Such type of agreement is key for a sector like the retail to be able to consistently perform its Environmental Footprint. One of the significant differences with traditional corporate footprint is that assessment and reporting for OEF goes beyond the traditional carbon footprint and includes impact categories such as water footprint, pressure on resources as well as impact on human health through environmental pollution. Pressure on biodiversity or deforestation throughout the supply chain is also included.

292
Arla Foods Environmental Profit and Loss Account (E P&L) - Organisational LCA with Monetarisation
J. Schmidt, 2.-0 LCA consultants; A. Flysjö, Arla Foods
Arla Foods is among the world's largest dairy companies. To document the total life cycle environmental impact of their product portfolio, Arla Foods has conducted an Environmental Profit and Loss Account (E P&L). The E P&L expresses Arla Foods' environmental impacts in monetary units, in addition to the underlying physical units. The functional unit of the study is Arla Foods' product portfolio in 2014. Arla Foods intends to using the results to evaluate their environmental strategy and in various communications. This paper discusses the results and learnings from the E P&L. Especially, the similarities and differences with product LCA as well as the added value of monetarising the impacts are discussed. An E P&L can be described as a means of placing a monetary value on the environmental impacts along the entire supply chain of a given business. The only difference between an organisational LCA (OLCA) and an E P&L is that the E P&L uses monetarisation as weighting in the life cycle impact assessment, which is commonly not done in LCAs and OLCA. The study includes all Arla foods' sites (99 sites in 12 countries). Production and use of raw materials, energy carriers, packaging and transport are included, as well as treatment and utilization of by-products and wastes. In addition, products and services not directly used in production, such as computers, furniture and travelling are covered. The downstream parts of the life cycles (retail and consumers) are also included. The study presents results calculated using both consequential and attributional modelling in the life cycle inventory. Indirect land use changes are included. The monetarised impacts, i.e. the investigated externalities, can be compared to Arla Foods revenue at 10,600 million EUR2014, which indicate the created value. When monetarising the impacts, the consequential and attributional approaches show a contribution at 1840-5850 and 2240-4980 million EUR respectively. The intervals represent different valuation methods. The consequential results are generally higher than the attributional. This is because they include indirect land use changes and thereby a significant impact on nature occupation (biodiversity). The E P&L gives a broad and deep insight in the impacts from the full life cycle of Arla Foods product portfolio, and it provides a good basis for comprehensive sustainability reporting and for identifying options for improving the performance and reducing the impact.

293
Does ex ante application undermine the usefulness of LCA?
M. Villares; J. Guinee, University of Leiden / Institute of Environmental Sciences; A. Mendoza Beltran, CML Leiden University
Introduction\nIncentives for exploring options for safe recovery of metals from WEEE include:\n• Increasing development driven demand for metals\n• Wastefulness of metal loss into the environment\n• Deleterious environmental effects of unsafe disposal\nBioleaching, a natural process mediated by micro organisms, may become a promising emerging technology contributing to safe secondary metal recovery from WEEE.\nInitial experimental bioleaching results on WEEE printed circuit boards show efficient metal recovery yields.\n\nMethod\nLCA methodology was applied at an early stage to the novel bioleaching process to embed it in a life cycle context, linking it to upstream and downstream flows.\nA short term future scaling up scenario was defined using a proxy technology and estimated data.\nEnvironmental hotspots of this scenario were identified and its environmental impacts were compared with those of a current industrial pyrometallurgical technique.\n\nResults\nPotential hotspots were related to energy and material inputs for the bioleaching process and solvents for copper recovery.\nComparison with an existing technology returned an inferior environmental performance, even after further optimisation.\nThese results could not be considered robust given the precociousness of application, yet they served as valuable preliminary information.\nThe uncertainties also prompted further enquiry about the chosen product system boundary and the comparability of the technologies.\n\nConclusion\nThe ex ante application of life cycle assessment on an emerging technology created new knowledge on its potential development.\nApplying ex ante LCA and an exploratory scenario brings a systematic rigour and discipline to an ambiguous situation.\nThough imprecise with much conjecture involved, it is a valid mock-up of a plausible future providing useful provisional insights to be built upon.\n• Despite uncertainties, LCA displays potential environmental hotspots. \n• The developmental challenges for the emergent technology gain definition at an early stage. \n• The LCA approach broadens the research scope, bringing a systems approach, long term view, environmental aspects, and alternative perspectives on the novel technology to the research domain. \n• Ex ante LCA + exploratory scenario is of great service as a developmental design tool.

Developing life cycle sustainability indicators for setting up a new carbon fiber recycling sector
B. Pillain, University of Bordeaux / Institute of Molecular Sciences ISM The Life Cycle Group CyVi; E. Gemechu, University of Bordeaux / Institute of Molecular Sciences ISM; G. Sonnemann, University of Bordeaux / Institute of Molecular Sciences ISM The Life Cycle Group CyVi
Carbon fiber reinforced plastic (CFRP) consumption has been increasing over the past decade in sectors such as aeronautic, aerospace, automotive or wind energy. The trend also predicted to increase in the future, inevitably there will be a large amount of waste from the CFRP manufacturing process and its use. This urges for the need to establish and implement a sustainable recycling sector focusing on carbon fibers. With this context, the SEARRCH (Engineering Sustainability Assessment Research for Composites with High Recycled value) project aims at defining a list of Key Sustainability Performance Indicators (KSPi) inherent to the CFRP recycling industry in order to help stakeholders make their choices easily. As research partner of SEARRCH project, in this paper we focus on the selection of suitable indicators and assess their relevance to meaningfully define the CFRP recycling sectors' sustainability. The selection of relevant indicators was carried out based on an extensive literature review on existing methods and indicators used to assess the three aspects of sustainability. Environmental indicators were based on life cycle assessment (LCA). The frequency of use was considered as the main selection criterion from a number of indicators analysed. The socio-economic aspects of carbon fiber recycling sectors were addressed by considering an additional resource perspective, which is based on recent publication by Sonnemann et al., 2015. The results show that global warming (IPCC) acidification (Accumulated Exceedence), and human concern (USEtox) are the most relevant environmental indicators. Three indicators were also

identified to assess the socio-economic aspect of carbon fiber recycling from resource perspective. These are: supply risk due to geological availability (CML -Resource Depletion), supply risk due to geopolitical factor (GeoPolRisk) and importance (waste flows obtained from the material flow analysis (MFA)). For the economic aspects the net present value (NPV) that allows to consider stakeholders and potential investor point of view was selected. The paper highlights the possibility to bring aspects of criticality assessment as a new resource dimension that can be integrated with the traditional environmental assessment tools to address the sustainability performance of a newly created carbon fiber recycling sector. The future perspective is to apply the proposed indicators to a specific case study.

295
Assessing resource efficiency of production processes in a Life Cycle approach: the case of metal working processes
L. Schebek, TU Darmstadt / Material Flow Management and Resource Economy; A. Campitelli, B. Becker, TU Darmstadt / IWAR
Enhancing resource efficiency is a major goal of sustainable development. Manufacturing industries are responsible for around 25 per cent of the primary resource use and a third of the global electricity use [1]. As to metalworking industries in Germany, major potentials to increase energy and resource efficiency at company have been identified in previous studies. However, the implementation of these potentials is slow. In the research project 'TU Darmstadt learning factory–resource efficiency in production–pilot project-machining processes'[1] we investigated technological parameters and indicators as basis for guidance documents for metal working companies. The focus of our research project was 1) to detect the relevant parameters of machining processes (drilling and milling) on company level, which have a high impact on resource and energy consumption and 2) to create concepts of indicators for assessing resource efficiency of machining processes on life cycle level. European resource policy defines the term of resources as materials extracted from nature but also the carrying capacity of the natural environment [2]. Given this definition, Life Cycle Assessment is a suitable methodology to assess resource consumption as well as flows to the environment connected to impact categories. However, enhancing resource efficiency in the manufacturing industry requires robust and transparent indicators of resource consumption which can be easily communicated within companies. Using the LCA as assessment methodology we found out that during the examined machining processes the consumption of electricity, compressed air, cooling lubricants and the MQL oil are relevant parameters for resource efficiency. On this basis, we derived indicators which can be used for metal working processes on the company as well as on policy level. References [1] UNEP. 2011. Manufacturing. Investing in energy and resource efficiency. http://www.unep.org/greeneconomy/Portals/88/documents/ger/GER_7_Manufacturing.pdf Accessed 23.11.2015. [2] European Comission. 2010. How to improve the valorisation process of End-Of-Life vehicles? LCA as a tool to help decision
S. Belboom, University of Liège - Chemical Engineering / Chemical Engineering PEPs; G. Lewis, P. BAREEL, Comet Traitements SA; A. LEONARD, University of Liege / Dpt of Chemical Engineering PEPs
This paper undertakes an environmental evaluation of hybrid vehicles recycling, using industrial data from Comet Traitement SA in Belgium. Three business lines have been modelled and analysed. The first one is relative to the business as usual with a dismantling to recover batteries and engines followed by shredding and post shredding treatments. The second one considers, in addition, the removal of electronic control units (ECU) before shredding followed by same steps than in the first line and the last one is relative to the additional removal of big plastic parts before shredding and business as usual post shredding treatments. Environmental impacts are assessed using both attributional and consequential LCA methodology both ILCD 2011 midpoint and ReCiPe 2008 methods.This study tends to answer this question: "Are the recovery of plastics and ECU prior shredding environmentally relevant in the end-of-life vehicle recycling process?". Using these environmental impacts results, important steps of recycling in both alternative routes will be highlighted. This study will also allow a comparison between these routes using several environmental criteria. This information could be coupled with economic costs of this dismantling and will give clues relative to this implementation of processes in Belgium and then information for policy decisions.\n Removal of ECU and plastics before shredding show an environmental gain in all categories compared to the business as usual scenario but differences are non-significant, lower than the uncertainty of the results, excepted for ECU where it depends on the yield valorisation. Concerning plastics, additional environmental gain is always negligible. This LCA shows the limit of dismantling in terms of environmental benefits and the highlights given by this tool for policy making. \n

Ecotoxicological assessment and water quality monitoring in support of marine and freshwater legislation in Europe

297
Marine contaminants and biological effects assessments for policy purposes; OSPAR's work at the regional scale
J. Foden, OSPAR; T. Burgeot, IFREMER / Department of Biogeochemistry and Ecotoxicology
This talk will provide a policy perspective, presenting OSPAR's work in assessing contaminants and biological effects in the marine environment, at the regional-scale. It will highlight how OSPAR's Contracting Parties of the North-east Atlantic maritime area cooperate to share the burden of monitoring and assessment. Data are freely available from an ICES data portal, and are used by OSPAR, HELCOM, AMAP and Expert Groups in the management of chemical and biological data for regional marine assessments. OSPAR's expert group conducts and publishes annual assessments of contaminants (http://www.ospar.org/work-areas/cross-cutting-issues/cemp). The talk will describe OSPAR's Intermediate Assessment 2017 (IA2017) and its constituents of 'common indicator' and 'thematic' assessments. The dual purpose of the IA2017 as a 'roof report' to assist OSPAR Contracting Parties that are EU Member States in their reporting commitments for the EU's Marine Strategy Framework Directive will be explained.

298
SIMONI: Smart integrated monitoring of the water quality
R. van der Oost, Waternet / Onderzoek en Advies; G. Sileno, Waternet / Research and Development; L. Moria, Waternet / Water Systems; M. Thao Nguyen, Waterproef; M. Suarez Munoz, University of Amsterdam IBED Institute / Institute for Biodiversity and Ecosystem Dynamics
At the Waternet Institute for the Urban Water Cycle an alternative effect-based chemical monitoring strategy has been developed over the last five years. The objective of this SIMONI strategy (Smart Integrative Monitoring) is to get more information on the water cycle quality for less money than traditional methods (e.g. Water Framework Directive). This project, that aims to bridge the gap between scientific research and regular field monitoring, combines passive sampling with standardized *in situ*, *in vivo* and *in vitro* bioassays. The first version of the SIMONI model for classifying microchemical risks of surface waters will be demonstrated. A simple 'Toxicity traffic light' is developed for policymakers and regulators, indicating low, potential and high risks of microchemical pollution for the ecosystem. Phase 1 of the model is a hazard identification that makes the distinction between low and potential ecological risks. Hazards are mainly determined with a suite of reliable, fast, user-friendly and inexpensive bioassays. The selection of endpoints for toxicity profiling was directed towards the indication of potential risks from a broad spectrum of chemical micropollutants to aquatic organisms (e.g. nonspecific toxicity, endocrine disruption, antibiotics activity, genotoxicity, oxidative stress, dioxin-like toxicity). In order to indicate ecological risks, effect-based trigger values (EBT) were designed for all relevant bioassay responses. A three-step approach was used for EBT development, aquatic toxicity data search, species sensitivity distribution of toxic equivalents (TEQ), and benchmark field studies. Measured bioassay data were incorporated into a simple model that compares the responses with their EBTs and adds a weight factor to different types of bioassays, thus generating a quantitative hazard classification of the entire mixture of micropollutants. Results of field monitoring studies will be presented that demonstrate the feasibility of this strategy for identifying hot-spots of chemical pollution. It appeared that highest ecological risks occurred at the agricultural greenhouse areas, most likely due to pesticide emissions, while lower risks were observed in waters receiving wwtp effluents. Due to low costs and high relevance, this model has the potential to become the first bioanalytical strategy to be applied in routine water quality monitoring. *Key words: toxicity profiling, passive sampling, ecological risk assessment*

299
Environmental monitoring: industry requirements and needs
I. Nilssen, Statoil ASA and Norwegian University of Science and Technology / Environmental Technology
Environmental monitoring related to the offshore petroleum industry has traditionally been carried out through ship campaigns with varying temporal and spatial resolution. Typical parameters measured are physical parameters such as grain size and total organic material (TOM), chemical parameters such as heavy metals and hydrocarbons as well as biological parameters such as taxonomy, species diversity and condition. National requirements are highly variable but the main purpose is to define the polluted area and trends within and between various areas. Linking environmental monitoring to the industry's relevant risk picture, however, traditional monitoring may not be the most cost-efficient. The reasons are several and they all originate from the need of flexibility. The activities on the different assets vary, the nature of the discharges varies and they are located in areas with various environmental conditions. In a risk-based system, monitoring, risk modelling and mitigation measures are the three cornerstones. Modelling can help optimising the environmental monitoring programme by focusing on the most critical aspects and sampling strategy. New technology has led to new opportunities for a holistic environmental monitoring approach adjusted to purpose, object or specific area of interest. A variety of fixed and mobile sensor

platforms now enables gathering of relevant amounts of data with the temporal and spatial resolution needed. Combining monitoring and modelling with appropriate mitigation measures, targeting the most critical component(s) of the discharges, will lead to improved environmental performance.

Use of effect-based tools in the context of the Water Framework Directive (WFD) – presentation of past and on-going projects
S. Schaan, European Commission - DG Environment / Water unit
Effect-based tools are drawing increasing interest in the context of the implementation of the Water Framework Directive (WFD), in particular because of their ability to detect effects caused by mixtures of pollutants and because of their potential use to bridge the gap between a substance-by-substance risk assessment (used to assess the chemical status in the WFD) and the integrative biological indicators used to determine WFD ecological status. This presentation will describe past and on-going activities on the use of such tools led under the Common Implementation Strategy for the Water Framework Directive, and outline some future perspectives.

301
Developing a framework for the assessment of contaminant impacts in marine ecosystems
K. Hylland, University of Oslo / Department of Biosciences; I. Davies; M. Gubbins, Marine Scotland; C. Robinson, Marine Scotland Science; T. Lang, Thünen Institute; D. Vethaak, DELTARES / Marine and Coastal systems; C. Martinez-Gomez, Instituto Español de Oceanografia / Marine Contamination and Biological Effects; T. Burgeot, IFREMER / Department of Biogeochemistry and Ecotoxicology; J. Thain, Cefas
European marine ecosystems are subject to a range of pressures, including fisheries, habitat change and contaminant inputs. Available data suggest that contaminants affect marine organisms, particularly linked to inputs from large rivers and areas with high offshore activity. Despite such knowledge, there has been no widely accepted guideline by which to assess contaminant effects. An integrated framework has been developed by ICES/OSPAR working groups (WKIMON/SGIMC) to enable an assessment of contaminant impacts in coastal and offshore ecosystems. The framework is based on assessment criteria for contaminant concentrations and effect methods, i.e. identifying background assessment concentrations (BACs), and environmental/ecotoxicological assessment criteria (EACs) for selected contaminants and biological effects methods. The framework comprises abiotic and biotic components, i.e. sediment, fish, mussels and gastropods. In addition, additional measurements to support the assessment, e.g. hydrographical data, are included. A methodology has been developed to combine results from different matrices/species and analytical methods, producing indices that may be integrated across methods/mechanisms of toxicity, locations or regions. The index for any single location or region using the framework can be integrated with assessments performed within the Marine Strategy Framework Directive.

Panel discussion

Science Integrity and Publication Bias

303
Introduction to Research Integrity – Academic Perspective
M. Zeegers, Maastricht University
There is a broad consensus among academic institutions, government and industry that more systematic and explicit attention should be paid to scientific integrity. Responsible Conduct of Research (RCR) is not only an ethical responsibility. It is also a relevant operational priority in times when there is increased scrutiny from government, regulatory authorities stakeholders and the public, and the reproducibility of research findings appears to be low. Previous studies, however, have shown however that on average 2% of scientists conduct fraud and 34% are involved in Questionable Research Practices (QRP), which due its high frequency may have a larger organizational impact. This whistleblowing presentation discusses the current play-field and proposes some policy changes to reduce 'research waste'.

304
Research Integrity Codes – An Overview in a Governance Perspective
L. Sydnes, University of Bergen
Science is an enterprise that is based on trust and transparency. Knowledge is supposed to be generated, communicated, and distributed a verifiable and provable way that is assumed to prevent fraud and other dubious practices and make sure the science community is self-correcting [1]. Of course we know that the system has never been completely flawless, but overall it has functioned so well that most knowledge made publicly available has been reliable and trustworthy. However, the last couple of decades we have witnessed a sharp increase in the number of violations of this vulnerable and delicate system. This is alarming because the value and benefits of research as well as the sciences' ability to serve society and humankind are vitally dependent on the trustworthy researchers performing investigations with integrity [2]. To meet this crucial challenge and try to curb scientific misconduct, discussions and developments of Code of Conducts have increased considerably in recent years and made the science community aware of the need to be proactive and teach and reflect on what constitute research integrity as the framework for science changes. In the lecture cotemporary challenges and initiatives relevant to the theme will be presented, discussed and highlighted. Attention will be drawn to available resources, including ICSU's compilation of documents on the web [3], IUPAC's living-code concept [4], and publications resulting from conferences [5], which are of value for researchers and teachers alike. *References* [1] CFRS brochure; *Freedom, Responsibility and Universality of Science*, ICSU, Paris France; **2014**; http://www.icsu.org/freedom-responsibility/articles_and_letters. 305
Sound Science – Industry Perspective
D. van Wijk, Euro Chlor
The chemical industries and their products are essential for societal prosperity and innovation. Innovation depends on effective scientific progress, which is also a key determinant in how the assessment of chemical safety for human health and the environment is performed in order to enable evidence-based decision-making. Therefore the scientific investigation and publication process and the utilisation of scientific results are essential for industry and the entire society as a whole.\nIn a society with different interests, science has to provide the level playing-field and common ground and therefore it is essential that science integrity is maintained at all levels during science's route from concept to law. In practice though, there are vulnerabilities in the process that may occur at different application levels, in a multitude of different ways. To identify and illustrate good and bad practices at all levels from investigation to policy, a matrix approach has been developed which will be discussed.\nAs a worst-case example, the incorporation of poor studies into poorly reviewed journals that are 'cherry-picked' into review articles, may lead to selection by a prejudiced scientific committee for inclusion by legislative bodies who are motivated by popular opinion (based on tabloid/ social media 'scare-mongering'). This may result in regulations that incorrectly restrict societal use of essential substances. The presented matrix can help to identify those best practices that are required at each stage in directing impartial, apolitical and scientifically correct, high quality decision-making.

306
Perspectives of Academic Journals on Scientific Integrity and Publication Bias
G. Burton, University of Michigan / School of Natural Resources   Environment
There is an increasing awareness of a lack of scientific integrity and publication bias in peer-reviewed journals. This has been documented in the highest ranked journals. Retraction rates have dramatically increased due to plagiarism or falsification of data. This increasing trend is likely due to both improved detection methods and pressures to publish. The rates of bias are less clear and more difficult to measure and are linked to sector affiliation, gender, age, institutional reputation and geography. The majority of those surveyed support the double-blind review process to reduce bias, but there is no consensus across scientific journals. Promoting publication from the disenfranchised is a noble call – but requires concerted efforts from scientists and professional scientific societies. ET&C is addressing these challenging issues via a number of avenues, including their "Perspectives" columns, routine dialogue with their Editors to identify and respond to bias, and actively recruiting submissions from under-represented regions. ET&C will continue to be vigilant in maintaining its high level of scientific integrity, and will continue to look for methods to reduce the inherent human tendency of bias. Organizing a mentoring approach for scientists in under-represented regions has been of an *ad hoc* nature and should be expanded in the future.

307
SETAC Ethical Code of Conduct - followed by panel discussion
P.D. Guiney, Retired- S C Johnson & Son, Inc / Molecular and Environmental Toxicology Center
SETAC has maintained and upheld a Code of Ethics for many years. In 2015, the SWC revisited this Code of Ethics as part of their Long Range Planning process and decided to focus on this important topic as a key initiative. A Scientific Integrity Subcommittee was formed under the auspices of the Global Communication Committee. The Steering Committee for this new group met and discussed at least three issues we thought SETAC could significantly influence in

a positive way. First, we felt that there was an increasing lack of personal integrity. Certainly there are institutional biases, mostly in the organizations that are supposedly "protectors of the environment." But underlying that is the question of personal integrity. What are the data really telling us? We need to know; good, bad, and ugly. Secondly, we felt that there was a general lack of understanding industry. Most people have "things" but don't realize all that is involved in the manufacture, distribution, sale, and end-of-life management of "things." There has been an increasing fervor from the business sector of SETAC that there is industry bias. This is an issue that SETAC with its long history of tripartite representation is in a unique position to address. Finally, is the issue of publication bias including what might be called the rise of the on-line journal. Many SETAC scientists get numerous emails requesting that they publish their work in speedy on-line journals at low costs. The on-line publishing world discovered a great "pay to play" model, where almost anyone can get almost anything published in a "peer reviewed" journal. Of course, their Impact Factors are at or below zero, but many times that's irrelevant. Judges don't know about Impact Factors, so a publication in any journal holds a lot of weight in a court of law. When you are in a "publish or perish" institution, any journal is better than none. In addition, because of the plethora of journals, it is becoming nearly impossible to find good reviewers for papers. The current Code of Ethics also mixes two distinct issues: namely personal ethics and scientific ethics. In this context, personal ethics means how someone responds to someone else and scientific ethics means the quality of our research. SETAC has a duty to address both types of ethics. Our medium to longer term, is to separate the two types of (un)ethical behaviour. Thus we are proposing changes and enhancements to both the SETAC Code of Conduct and the Code of Ethics.

Persistent and mobile contaminants in the aquatic environment: how to identify, analyse and regulate a potential threat for drinking water resources (II)

318
How do chemical and environmental properties affect the retention of organic contaminants in urban watersheds?
A. Parajulee, Y.D. Lei, A. Kananathalingham, University of Toronto Scarborough / Department of Physical and Environmental Sciences; L.W. Yeung, University of Toronto / Chemistry; A.O. De Silva, Environment and Climate Change Canada; C.P. Mitchell, University of Toronto Scarborough / Department of Physical and Environmental Sciences; F. Wania, University of Toronto Scarborough / Physical and Environmental Sciences
Prominent characteristics of the urban landscape include impervious surface coverage and sewer networks that both serve to increase runoff delivery to streams and decrease infiltration. This can lead to rapid, often untreated inputs of contaminants to water bodies during snowmelt and rainfall. Of particular interest are how chemical properties and environmental properties interact during such events to influence contaminant delivery to streams. This study investigates the relative importance of chemical properties, urban infrastructure, and physiography on the transport of a broad range of organic contaminants in urban Canadian watersheds. In Toronto, Canada, we have three sampling sites in each of two watersheds that differ widely in their degree of urbanization, and hence the types and configurations of their land cover and city infrastructure. We measured dissolved and suspended sediment-bound streamwater concentrations of polycyclic aromatic hydrocarbons (PAHs), neutral and acidic pesticides, and benzotriazoles during two rainfall events and one snowmelt event. We also concurrently measured suspended sediment, dissolved and particulate organic carbon, and electrical conductivity. Preliminary results from one rainfall event show peak concentrations of particle-bound PAHs that are 20-94 times higher, and area-normalized fluxes 6 to 24 times higher, at the sites in the more urbanized watershed relative to the largely agricultural watershed. Furthermore, while these peak concentrations increase downstream in the urbanized watershed, there is little to no change in peak concentrations in the other watershed. The total watershed particle-associated PAH loading to Lake Ontario was also 25 times higher. We will additionally present the results of ongoing sample analyses that answer the following questions arising from these initial findings: (1) What drives the higher concentrations and loadings in the highly urbanized watershed? The explanation could be one or both of the following: first, that the urbanized watershed has greater within-watershed sources of PAHs and second, that the mostly agricultural watershed has a greater retention capacity for PAHs. (2) Are the observed patterns consistent across snowmelt and rainfall events, for all analytes, and why or why not?

319
Screening of organic contaminants in raw and drinking water from source to tap
L. Ahrens, Swedish University of Agricultural Sciences (SLU) / Dept of Aquatic Sciences and Assessment; R. Troger, Swedish University of Agricultural Sciences / Department of Aquatic Sciences and Assessment; P. Klöckner, Swedish University of Agricultural Sciences SLU; J. Lundqvist, Swedish University of Agricultural Sciences / Department of Biomedical Sciences and Veterinary Public Health; A. Rosenmai, T. Le Godec, Swedish University of Agricultural Sciences; A. Oskarsson, SLU Dept Biomed Sci Vet Publ Health / Dept of Biomed Sci and Vet Publ Health; K. Wiberg, Swedish University of Agricultural Sciences / Department of Aquatic Sciences and Assessment
The occurrence of synthetic organic compounds (OCs) in drinking water can pose a threat to human health. In this study, water samples were collected from drinking water source areas, inside a drinking water treatment plant (DWTP) and in finished drinking water from the surroundings of Uppsala, Sweden. The water samples were examined for 178 residues of pharmaceuticals and personal care products (PPCPs), perfluoroalkyl substances (PFASs) and pesticides. The contaminants were extracted using large volume solid phase extraction (SPE) and analysed using liquid chromatography coupled to a time-of-flight spectrometer (LC/TOF-MS). The main source of the targeted OCs was found to be a sewage treatment plant (STP) effluent. Concentrations decreased in two lake samples (lake Ekoln and Görväln) connected to the DWTP due to dilution effects and potential degradation. Within the DWTP, concentrations remained stable and contaminants were not removed efficiently with the conventional treatment

techniques of flocculation, sand filtration, granular activated carbon (GAC) and disinfection with UV light and chloramine. A pilot plant with membrane technology is ineffective as well, except when coupled to new GAC filter. Overall, the occurrence of contaminants in drinking water emphasis that more research is needed to develop appropriate and cost-effective treatment method for the removal of OCs and to improve our knowledge about their risks for human health and ecosystem.

320
Advanced water treatment assessment and novel monitoring techniques
S. Kools, KWR Watercycle Research Institute; K.A. Baken, KWR Watercycle Research Institute / CWG; I. Brüning, IAWR; G. Stroomberg, RIWA River Water Works
To control the emission of chemicals in the environment and to meet the requirements of the WFD, emissions of chemical compounds are more and more regulated, for example by the REACH and other substance specific regulations. Next to that, emission point sources of WWTPs are being upgraded towards the elimination of chemicals of emerging concern (CECs). More specifically, in the Rhine area, several communal waste water treatment plants aim to increase the removal of these CECs. Here, additional treatment steps such as advanced oxidation processes (AOPs) and/or in combination with Granular Activated Carbon (GAC) are being considered or have been implemented. Numerous studies describe the successful removal of substances in waste water, hence higher removal rates by these treatment steps. While the intention is to lower emissions of CECs, resulting transformation products may be overlooked. Concise information on the formation and toxicological relevance of transformation products is lacking and it is unclear to which extent transformation products contribute to overall toxicities of treated waters. This review will collate existing information on the risks of AOPs in the light of large scale applications of these new waste water treatment techniques. Also, the review will identify research questions that arise, specifically the impact of the formation of polar persistent transformation products on drinking water production. The review will highlight existing and novel monitoring techniques, both to identify toxicity as to recognize unknown and known chemicals. As drinking water utilities apply similar techniques for the production of safe and healthy tap water, information may be usable for different water managers and researchers.

321
Application of the novel Orbitrap-based gas chromatography-mass spectrometry technology to characterize emerging disinfection by-products in disinfected water.
C. Postigo, IDAEA, CID-CSIC / Environmental Chemistry; C.I. Cojocariu, Thermo Fisher Scientific; S.D. Richardson, University of South Carolina; P. Silcock, Thermo Fisher Scientific; D. Barcelo, IIQAB-CSIC / Dept Environmental Chemistry
About 50% of the halogenated material formed during water disinfection is still unknown[1]. Several chemical classes of low molecular weight **iodinated disinfection by-products (iodo-DBPs)** have been reported to be within the aforementioned unidentified fraction. The presence of iodo-DBPs in drinking water is of concern, because these compounds have been found to be in some cases *more genotoxic and cytotoxic* than their corresponding brominated and chlorinated analogues[1,2]. Recent developments in gas chromatography (GC)–mass spectrometry (MS) allow the use of high resolution-accurate mass (HRAM) Orbitrap mass analyzer to further explore and characterize the volatile and semi-volatile compounds present in the disinfection by-product (DBP) mixtures, providing the resolving power, mass accuracy, and sensitivity required for these tasks. In this context, the main goal of the present work was *to apply the GC Orbitrap MS technology to characterize iodo-DBPs in chlorinated and chloraminated DBP mixtures*. To this end, chlorinated and chloraminated DBP mixtures were generated from a reference aquatic natural organic matter (NOM) solution, i.e., Nordic Reservoir NOM, fortified with bromide (500 ppb) and iodide (50 ppb), and Llobregat river water, and analyzed with a GC-Orbitrap MS. Iodo-DBP characterization was based on HRAM data and fragment rationalization. The workflow applied allowed identification of up to 11 different iodo-DBPs in the DBP mixtures analyzed, including one new iodo-DBP. Overall, it could be also observed that iodo-DBPs were formed to a larger extent after *chloramination* of waters; however, the type of NOM, in terms of aromaticity, and the bromide and iodide content the water were found to be relevant factors affecting the formation of these compounds during disinfection treatments.

322
Do cytostatic drugs reach drinking water? The case of mycophenolic acid
H. Franquet, Environmental Chemistry; F. Ventura, IDAEA-CSIC; M. Boleda, Aigues de Barcelona / Organic Chemistry Department; S. Lacorte, IDAEA-CSIC / Environmental Chemistry
Mycophenolic acid (MPA) has been identified as a new river contaminant according to its wide use and high predicted environmental concentration in the river (PEC_{river}). In Catalonia (NE Spain), its consumption ranged from 4.7 to 4.9 tons during 2010-2012, which represents 40% of the total drugs administered, and the calculated PEC_{river} was 77.4 ng L^{-1} [1]. Therefore, the aim of this study was to monitor the impact of MPA in a drinking water treatment plant (DWTP) that collects water downstream Llobregat River (NE Spain) in a highly densified urban area. An UPLC-MS/MS method was developed and validated to quantify this compound in water samples. During a one week survey MPA was recurrently detected in the DWTP intake (17 - 56.2 ng L^{-1}). The presence of this compound in river water was associated to its widespread consumption, high excretion rates and low degradability. As MPA was always detected after 7 consecutive days, its fate in waters at each treatment step of the DWTP was studied and complete removal was observed after pretreatment with chlorine dioxide. In addition, degradation experiments were performed using ClO_2 at different concentrations and degradation products were identified. MPA does not reach drinking water considering the current treatments carried out in this particular DWTP. However, its reiterative presence associated with its consumption in anticancer treatments is of relevance to highlight the importance of monitoring this compound.
[1] Franquet-Griell, H., Gomez-Canela, C., Ventura, F., Lacorte, S., 2015. Predicting concentrations of cytostatic drugs in sewage effluents and surface waters of Catalonia (NE Spain). Environ. Res. 138, 161-172.

Pushing nanoparticle studies to the limit - working at environmentally relevant concentrations and with complex matrices (I)

323
Detection and quantification of Carbon Nanotubes along the life cycle, using a thermo-optical method
A. John, Institute of Energy and Environmental Technology IUTA eV / Air Quality   Sustainable Nanotechnology; M. Renker, Institute of Energy and Envionmental Technology eV   IUTA; B. Stahlmecke, Institute of Energy and Environmental Technology IUTA eV / Air Quality   Sustainable Nanotechnology; T.A. Kuhlbusch, Institute of Energy and Environmental Technology e.V. - IUTA / Air Quality   Sustainable Nanotechnology; C. Nickel, Institute of Energy and Envionmental Technology e.V. - IUTA / Air Quality   Sustainable Nanotechnology
Carbon nanotubes (CNT) are already used as additives to various structural materials, due to their extraordinary thermal conductivity and mechanical and electrical properties. A release during production, handling, usage, transport or end of life seems possible. Therefore, the detection of CNT along the whole life cycle in different compartments is very important to asses a potential risk for human health and the environment. Depending on the application and release mechanisms CNT may enter different environmental compartments in varying concentrations. Thus, different requirements for the sample preparation and detection have to be considered. One main challenge dealing with the detection of CNT in the different environmental compartments is the high background concentration of natural carbon based materials and the differentiation between CNT and these materials. By using a thermo-optical method a differentiation between different types of CNT and natural carbon based materials and CNT was possible. For this, we adapted a thermo-optical carbon analysis which is routinely used to determine elemental carbon from filters probed with e.g. ambient or workplace air. This method determines total carbon (TC) and uses a specific temperature protocol to fractionate TC into organic carbon (OC) during first temperature steps in pure helium and elemental carbon (EC) during the second temperature steps in a helium/oxygen atmosphere. For the detection of CNT an established NIOSH5040-like protocol „quartz.par" was modified. Two additional temperature steps were integrated in the low temperature EC section to achieve a good differentiation between CNT and natural carbon based materials, like humic acids. During this presentation results for different life cycle stages are presented, starting with the release of CNT in air from products during mechanical stress, the detection of CNT in water and soils, the uptake into organisms and the release of CNT during incineration at the end of life. The results were generated within the CarboLifeCycle project which was founded from the German BMBF, grant 03X0114D.

The devil is in the details: Tomography to characterize nanoparticle-plant interactions at low ppm exposure concentrations
F. Schwab, CEREGE / Interfast   Transferts; A. Avellan, CEREGE; A. Turner, Duke University; C. Santaella, CNRS/CEA/Aix-Marseille Université / Bioscience and biotechnology Institute of Aix Marseille; J. Bottero, Labex Serenade/CEREGE/Aix-Marseille Université; J. Rose, CEREGE / Interfaces Transferts; C. Levard, CEREGE; M. Auffan, CEREGE / International Consortium

for the Environmental Implications of Nanotechnology
The current understanding of the uptake processes of engineered (nano)materials (ENMs) in plants strongly relies on two-dimensional visualizations of (nano)particles in or on plant tissue, and quantitative analyses of plant digestates. Most of these techniques require the plants to be exposed to very high ENM concentrations (tens to hundreds of mg kg^{-1}), due to the highly complex background matrix of plant tissue, and the low ENM uptake rates of many plants. Such 2D visualizations and uptake concentrations provide valuable information on the mechanisms of acute ENM toxicity, and on ENM affinity to plant tissue. However, it is challenging to use 2D-imaging and digestate analyses to answer questions on the extent and mechanism of internalization of ENMs, or on ENM-plant interactions at environmentally more relevant, subacute exposure concentrations in complex matrices. Therefore, we developed, tested, and validated minimally invasive 3D X-ray micro- and nano-tomography methodologies to semi-quantitatively analyze the nanoparticle distribution and anatomical adaptations to the exposure of ENM in higher plants. Using *Medicago sativa* and *Arabidopsis thaliana*, we studied the ENM distribution of non-dissolving (-/+ nano-Au) nanoparticles. To broaden the understanding of the physiological adaptations of the plants to the ENM exposure, 2D µ-X-ray fluorescence spectroscopy (µXRF) was used. The results show that plants exposed to non-dissolving nano-Au, even at subacute concentrations in the low mg kg^{-1} range, exhibited considerable anatomical changes and adaptations in *M. sativa*. In *A. thaliana*, positively charged nano-Au accumulated in a greater extent preferentially in the border cells of the root cap featuring negative functional groups, and negatively charged nano-Au accumulated to a lesser extent in the apoplast of exposed roots. These findings demonstrate the suitability of 3D X-ray micro- and nanotomography for the analysis of ENM distribution in plant tissue at low ppm exposure concentrations, confirm previous hypotheses about the protective effect of root border cells against positively charged ENMs, and reveal previously unknown changes of the root anatomy of agriculturally relevant legumes upon ENM exposure. 325
Overview of advanced data treatment techniques in spICP-MS using Nanocount
G. Cornelis, University of Gothenburg / Department of Chemistry and Molecular Biology
Single particle ICP-MS has grown fast in recent years as a technique to analyse nanoparticles size and number concentration in particularly difficult samples and at environmentally relevant concentrations. Much of the effort has been in developing techniques for robust data treatment, which is required at different stages to arrive from raw, time-dependent data to a particle size distribution (PSD). The current work presents an overview of previously developed data treatment techniques for particle/dissolved signal discrimination and nebulisation efficiency. The techniques are compared with the FAST spICP-MS approach discussing how such data can be processed and the limits of several approaches. Moreover, a new drift correction procedure is presented, in which longer term drift is corrected. Advanced data treatment techniques offer a number of opportunities not available when using commercially available software preovided by ICP-MS manufacturers. Most notably, reductions in false negatives and positives are to be expected, which is especially relevant when measuring relatively low particle numbers. However, the advanced techniques require much user intervention in the form of expert knowledge, a situation that is probably preventing their routine application.

326
Optical nanoparticle analysis for size and shape at environmentally relevant concentrations
S.R. Thompson; J. Yuan, University of York / Phyics; A. Boxall, University of York / Environment Department
In recent years, environmental nanoparticle research has shifted away from understanding the specific effects of specific nanoparticles on specific organisms at unrealistically high concentrations, and towards more mechanistic studies aimed at discovering the causes of nanoparticle toxicity rather than the effects, at more environmentally relevant concentrations. One of the major challenges with running these studies is the difficulty of confirming the state of nanoparticles once they've been released into the system – at environmentally relevant concentrations the only commercially available system capable of making such measurements is a single-particle ICP-MS setup. This is large and non-portable, expensive, and isn't capable of inferring much about the shapes of the particles it measures. We present a novel optical scattering device, which can be built for under £5,000 (€7,000, US$7,500), miniaturised to fit inside a medium-sized suitcase, operated in-situ using a laptop and an automotive battery, and which can take statistically robust measurements of nanoparticles at concentrations 2 orders of magnitude lower than current optical techniques, allowing it to rival detection thresholds in current sp-ICP-MS setups. The system is also capable of taking simultaneous size and shape measurements of nanoparticles.

327
Single-particle ICP-TOF-MS provides elemental ratios on an individual particle level for the identification of cerium oxide nanoparticles at environmentally relevant concentrations
A. Praetorius, University of Vienna / Department of Environmental Geosciences; A. Gundlach-Graham, E. Goldberg, ETH Zurich; W. Fabienke, University of Vienna / Department of Environmental Geosciences; J. Navratilova, A. Gondikas, University of Vienna / Environmental Geosciences; D. Guenther, ETH Zurich; F. Von der Kammer, Vienna University / Department of Environmental Geosciences; T. Hofmann, University of Vienna / Department of Environmental Geosciences
Analytical methods to detect, quantify and characterise CeO_2 NPs in soils and surface waters are urgently needed to assess environmental exposure and risk of these materials. The main challenge in the detection of engineered CeO_2 NPs in environmental matrices is the presence of natural Ce-containing minerals of similar size range at concentrations several orders of magnitude above expected levels for engineered CeO_2 NPs. A promising approach to identify engineered CeO_2 NPs against the natural background is to take advantage of the different element ratios of natural versus engineered Ce-containing NPs. For example, the Ce to La ratio is expected to be relatively stable at about 2:1 in natural environments, while engineered CeO_2 NPs show a Ce:La ratio of about 4000:1. However, due to the much higher natural Ce-levels compared to engineered CeO_2 NP concentrations in the environment, the sensitivity gained from the element ratio alone is too low to yield any detectable results when performing conventional bulk analysis on soil samples. We therefore have to move towards an assessment of the elemental ratios on an individual particle level. We here present a new approach, using a prototype ICP-TOF-MS instrument, coupling a conventional ICP-MS with a time-of-flight (TOF) instrument, enabling the simultaneous measurement of multiple elements at high time resolution. The applicability of this method for the detection of engineered CeO_2 NPs in complex samples is demonstrated on a series of natural soils spiked with different concentrations of CeO_2 NPs. Our results show, that we can clearly differentiate between Ce- and La-containing natural particles and Ce-only containing engineered nanoparticles using the ICP-TOF-MS in single-particle mode. Furthermore, a more advanced data analysis method based on a Machine Learning approach makes it possible to improve our detection by establishing elemental "fingerprints" of natural and engineered Ce-containing NPs based on 30 selected elements. This provides a more reliable analysis, especially for particle signals close to the detection limit. In this way we are able to confidently detect engineered CeO_2 NPs at ppb concentration levels. The new method represents an important advancement for the detection of ENPs in complex matrices at environmentally relevant concentrations and can likely be applied to a wide range of other ENPs in the future.

Application of single particle ICP-MS for the detection of nanomaterials in complex environmental samples
A. Gondikas, University of Vienna / Environmental Geosciences; F. Von der Kammer, Vienna University / Department of Environmental Geosciences; J. Navratilova, University of Vienna / Environmental Geosciences; A. Praetorius, University of Vienna / Department of Environmental Geosciences; G. Cornelis, University of Gothenburg / Department of Chemistry and Molecular Biology; M. Tharaud, Institut de Physique du Globe de Paris, Sorbonne Paris Cité, Univ. Paris Diderot; M. Hassellov, University of Gothenburg / Department of Marine Sciences; T. Hofmann, University of Vienna / Department of Environmental Geosciences
Regulatory efforts rely on nanometrology for the development and implementation of laws regarding the incorporation of engineered nanomaterials (ENMs) into industrial and consumer products. Therefore, advanced analytical techniques combined with appropriate sample pre-treatment methods are necessary for the isolation and analysis of nanomaterials in environmental samples. Environmental nanometrology unavoidably deals with materials of poorly-defined properties and in complex matrixes, in which nanomaterials may undergo significant transformations. It is therefore imperative to develop appropriate analysis protocols to understand the environmental dynamics of these materials. Single particle inductively coupled plasma mass spectroscopy (spICP-MS) has been suggested as a powerful tool for routine nanometrology efforts. However, this technique is not yet developed to its full potential and method development is required for different ENMs and natural systems. In this work, we apply several spICP-MS methods for the detection of titanium dioxide ENMs in natural surface waters and copper oxide ENMs in colloidal extracts from natural soil samples. In the former case we aim at overcoming the challenge posed by high Calcium concentrations and the isobaric interference of ^{48}Ca isotope on the most abundant ^{48}Ti isotope; although the natural abundance of the ^{48}Ca isotope is relatively low (0.19 %) compared to ^{48}Ti (73.8 %), Ca concentrations in surface waters are typically more than three orders of magnitude higher than Ti. In the latter case we adjust a spICP-MS method on the detection of CuO ENMs in soil colloid extracts, based on the characteristics of the soils. Overall, our work demonstrated the great potential of spICP-MS for the analysis of ENMs in

real-world environmental samples, while highlighting the limitations and challenges for two case studies. TiO_2 ENMs were successfully measured in the presence of high Calcium concentrations; however, this method is not able to measure TiO_2 particles smaller than 80 nm. CuO ENMs were also detected in spiked colloidal extracts; we choose a rather conservative approach for particle detection with the goal of avoiding falsely identifying background signal as engineered CuO NP particles. In this context, the need for comparing and correcting detected particles spikes against the presence of false positive spikes is also discussed.

Ecological traps for wildlife driven by pollutants

329

Eutrophic wetlands receiving effluents from wastewater treatment plants may act as ecological traps for endangered waterfowl

R. Mateo, U.C.L.M.-C.S.I.C. / Instituto de Investigacion en Recursos Cinegeticos; C. Gil, R. Guitart, Universitat Autònoma de Barcelona; A.J. Green, EBD-CSIC / Wetland Ecology

Animals can select habitat according to characteristics of the environment that correlate with better survival and reproductive success. In rapidly changing environments, these natural preferences can become ecological traps if the selected aspects of the habitat are accompanied with adverse environmental factors that affect individual fitness. Pollutants can be one of the important drivers of ecological traps nowadays. One of the potential scenarios that matches the concept of ecological trap are the eutrophic wetlands receiving effluents from wastewater treatment plants. These wetlands are highly productive and therefore attractive for waterbirds, especially those feeding on aquatic invertebrates like the white-headed duck (*Oxyura leucocephala*). These wetlands may also receive a myriad of pollutants from urban and industrial sewage that can accumulate and affect the ecology of the wetland and/or the health status of the waterbirds living there. Here we discuss the potential effect of these ecological traps for the white-headed duck and the marbled teal (*Marmaronetta angustirostris*), which are globally endangered species under threat in their remaining breeding areas such as Spain. The studied birds were marbled teals (n=28) and white-headed ducks (n=12), but also the invasive ruddy duck (*Oxyura jamaicensis*) (n=13) and their hydrids (*Oxyura leucocephala x jamaicensis*) (n=5) Organochlorine pesticides and PCBs were measured in liver and adipose tissue samples after extraction with hexane, clean-up with sulfuric acid and analysis by GC-ECD. Birds of the genus *Oxyura* showed higher organochlorine levels than marbled teal, especially in adipose tissue. No differences in organochlorine levels were found between each *Oxyura* species and their hybrids, between geographical areas (Andalusia, Valencia or Central Spain), by sex or by age. Several potential biotic (i.e. pathogens) and abiotic agents (i.e. chemical pollutants) may drive negative influences on the populations of endangered waterfowl through a mechanism in eutrophic wetlands that can be defined as an ecological trap. In addition to the mortality caused by botulism outbreaks and lead poisoning, white-headed duck shows a low reproductive outcome that could be caused by pollutants accumulated in the eutrophic lakes frequently selected by this species.

330

Can POPs contaminated sites be ecological traps for top predators?

J.E. Elliott, Environment Canada / Science Technology Branch; C. Nelson, University of British Columbia / Animal Science; D. Guertin; A.C. Huang, Forest Conservation Sciences

Numerous contaminated sites are documented in North America and many other parts of the globe. Among the main contaminants at such sites are legacy persistent organic pollutants (POPs) such as PCBs and organochlorine insecticides. Wildlife, including top-predatory birds and mammals may be attracted to such sites as the habitat often appears suitable. In the process, species such as river otters, can bioaccumulate POPs with potential consequences on health and fitness. Previously we used fecal samples collected from river otter communal marking sites (latrines)at the federal contaminated site of Victoria Harbour, BC, Canada, reported levels of PCBs that exceeded 9 mg/kg lipid, a published criteria for reproductive impairment in mustelids. Following up on that study, we again used scats to show variation in PCB exposure in time and space, and the population implications. In the present study again we used fecal sampling but combined with radio-telemetry to further investigate the exposure and to infer population level effects in river otters in that contaminated system. We also examine the question of whether the harbour constitutes an ecological trap situation. The implications of population structuring relate to the extent and impacts of contaminant exposure based on where the otters spend their time foraging and whether or not they are able to sustain a population in a contaminated site environment.

331

Are cities ecological traps for birds because of pollutants?

R. Scheifler, University of Franche-Comte / ChronoEnvironnement; J. Bailly, University of Burgundy / Biogeosciences; N. BERNARD, University of Franche-Comte / Laboratory of ChronoEnvironment; B. Faivre, University of Burgundy / Biogeosciences

Cities have higher temperatures, louder noise, lower parasite prevalence and higher levels of pollutants than rural habitats. They are considered as ecological traps because studies dealing with the impact of urbanization on bird fitness have shown that breeding parameters are affected. Among the mechanisms that may explain the responses of birds to urbanization, the impact of pollution has received little attention although cities are characterized by the circulation of many different pollutants. We hypothesized that NO_2 concentrations in the air and/or concentrations of non-essential trace elements (TEs) in blood were positively correlated to reduced reproductive outputs and/or nestling body condition in urban populations of Great tits (*Parus major*) compared to forest ones, while concentrations of essential elements in blood were negatively related to breeding outputs and/or individual performances if their concentrations exceeded threshold values or, on the contrary, if they did not meet physiological (homeostatic) requirements. Two cities and two forests were studied in eastern France. Each site received 150 artificial nestboxes that were inspected from March 20th to record breeding success from 2012 to 2014. In 2013, passive NO_2 samplers were put on nestboxes and the concentrations of 25 essential and non-essential elements were determined in 13-day old nestlings. In urban sites, breeding success, nestling growth rate and body condition were reduced. Atmospheric concentrations of NO_2 significantly differed between the four sites but no significant correlation was detected between NO_2 and biological parameters. Based on the results of a PCA on metal concentrations, we used the coordinates on the first axis as an index of richness in essential elements (REE), with negative values indicating high concentrations in essential TEs, and positive value indicating low concentrations. Brood body mass was positively correlated with REE. No other significant correlation was detected between REE and biological parameters. Our study brings new data about plasmatic concentrations of various essential elements in birds from urban and forest habitats and their positive relation to nestling body mass and condition. To our opinion, this is a clue to suggest that food availability and/or quality may be a causal mechanism for a reduced growth of nestling birds in urban areas, an issue that would need further investigations in urban ecology and in ecotoxicology in general.

332

Short-term and residual effects of pesticides on mosquito oviposition site selection and larval performance, and on aquatic community structure

C. Duchet, Institute of Evolution / Department of Evolutionary Environmental Biology; G.M. Moraru, University of Haifa / Department of Evolutionary Environmental Biology; K. Saurav, University of Haifa / Department of Marine Biology; A. Gershberg Hayoon, University of Haifa / Department of Evolutionary and Environmental Biology; R. Shapir, University of Haifa / Department of Evolutionary Environmental Biology; L. Steindler, University of Haifa / Department of Marine Biology; L. Blaustein, University of Haifa / Depatment of Evolutionary and Environmental Biology

Pesticides can have immediate toxic effects on targeted pest species as well as on non-target species for broad-spectrum pesticides. Broad-spectrum pesticides may also have positive effects on mosquitoes after the pesticide no longer has direct toxicological effects by altering the community structure – i.e. by reducing abundances of mosquito competitors and predators, and via a trophic cascade, increasing food resources for mosquito larvae. Moreover, in some cases, pesticides can act as an ecological trap for some taxa, attracting colonizer insects to habitats that are ultimately lethal for them. The present study was undertaken to assess mosquito oviposition habitat selection, mosquito larval performance and community structure alterations after pesticide applications. The experiment was conducted in outdoor mesocosms assigned to one of four treatments: (1) control – no pesticides; (2) *Bacillus thuringiensis israelensis*, a mosquito larvicide well-known for its selectivity for Nematoceradipterans; (3) temephos, a mosquito larvicide of the organophosphate class; (4) pyriproxifen, a pyridine-based pesticide of the Insect Growth Regulator (IGR) class. All three of these pesticides have short activity periods. Invertebrates were sampled 2 days before treatments, 4 and 7 days after treatment and then, every two weeks for a period of 2 months. Environmental parameters (water temperature, pH, conductivity, chlorophyll *a*) were measured in every mesocosm on each sampling date. Mosquito oviposition was monitored every 3 days. After applications, the number of egg rafts decreased in all the treated pools, but remained stable in the controls. Species richness and invertebrate abundance were also initially strongly reduced in the broad-spectrum pesticides (temephos and pyriproxifen) when compared to both the control and to the selective *B. thuringiensis israelensis* treatment, leading to an increase of chlorophyll *a* concentrations. One month after the treatment, mosquito oviposition was higher in the pyriproxifen-treated pools, in comparison to other treatments. However, mosquito larval survival remained lower in pyriproxifen-treated pools, even though pyriproxifen was not detected in the water samples 7 days after the application. Our results suggest that pyriproxifen appears to provide an ecological-trap, attracting mosquito oviposition due to altered community structure (fewer antagonists and more algal resources) but causing high mosquito larval mortality.

333

Are treated seeds an ecological trap for birds?

A. López Antia, Universiteit Antwerpen / Biology; J. Feliu, C.S.I.C; P.R.

Camarero, U.C.L.M; M.E. Ortiz-Santaliestra, IREC; F. Mougeot, C.S.I.C; R. Mateo, U.C.L.M.-C.S.I.C. / Instituto de Investigacion en Recursos Cinegeticos
Due to reductions in winter food resources, newly sown cereal seeds have become a key component of many bird species' diet, but these seeds are often treated with pesticides that may cause toxic effects. In order to complete an appropriate risk assessment, data on treated seed toxicity need to be combined with information about the risk of exposure of birds in the field. The aims of the present work are to characterize the exposure of farmland birds to pesticide-coated seeds in the wild, and to estimate the risk of poisoning of animals as a consequence of such exposure. To do this we analysed crop and gizzard contents of hunted partridges (n=189) to detect residues of pesticides used for seed treatment. Moreover, we measured the contribution of cereal seeds in the winter diet of partridges in order to assess the potential risk of exposure to pesticide-treated seeds. We also studied the abundance of pesticide-treated seeds available for birds in the field (n=48), the pesticides and their concentrations in these treated seeds, and the bird species that feed on them. Seed availability was influenced by the sowing method and the location within the field. Regardless of the sowing technique, there were more seeds on the surface in the headland (43.4 ± 5.5 seeds/m^2) than in the field centre (11.3 ± 1.2 seeds/m^2) (t_{151}=-4.67, p< 0.001). Six pesticides, mostly fungicides, were detected in the seeds collected from recently sown fields. 55.2 % of the seed samples contained detectable levels of pesticides, with tebuconazole being the most frequently found active ingredient. During the sowing period, 31 species were observed feeding on sown cereal seeds. We detected pesticide residues in the digestive content of 32.3% of the analysed red-legged partridges, including insecticides in a 3.7% of the analysed samples and fungicides in a 29.6% of them. As observed in seeds, tebuconazole was the most frequently detected pesticide (19.1% of the samples). Winter cereal seeds represented a 53.4% of the biomass found in the digestive content of red-legged partridges. The present study demonstrates that the use of pesticide-treated seeds constitutes an important way of exposure of farmland birds to pesticides, and that there exists a potential risk for these birds to suffer toxic effects from ingestion of treated seeds in the wild.

Mange, anticoagulants, and felids: Investigating immune response to low dose brodifacoum exposure

K. Horak; J. Kopanke, E. Musselman, K. Bennett, S. Vandewoude, Colorado State University; S. bevins, United States Department of Agriculture / NWRC
Anticoagulant rodenticides are used worldwide to control pest rodents in urban, suburban, and agricultural settings. This widespread use poses potential risk of exposure to non-target species. A study of bobcats and mountain lions near Los Angeles, CA detected a correlation between anticoagulant exposure and mange. Exposure to brodifacoum has thus been proposed as a potential mechanism for this effect in felids, though domestic cats have been shown to have high tolerance for anticoagulants. More research is needed to determine potential effects of brodifacoum that a cat would be exposed to by consuming non-target rodents. In this study, cats were offered 0.05 mg/kg brodifacoum once per week mixed into canned food and vaccinated with irrelevant antigen (ovalbumin, OVA) and adjuvant starting at week 1, with booster injections on weeks 4 and 8 to test effects of brodifacoum on recall antigen immune responses. Blood was collected weekly beginning on day 0 to additionally assess PBMC proliferation following exposure to ConA, KLH, and OVA. Whole blood was frozen for brodifacoum residue determination. None of the cats exhibited any clinical abnormalities during the study. Cats in both groups gained an average of 100g with no significant weight differences between the groups at the conclusion of the study (control= 4.06± 0.68 kg, brodifacoum= 4.08± 1.16 kg). Cats did not show any overt signs of anticoagulant intoxication for the duration of the study. Brodifacoum residue levels were determined from liver biopsies taken on day 77. Brodifacoum residues were 1806 ng/g in treated cats (stdev 105.7 ng/g) and not detected in control subjects (LOD 5.8, LOQ 19.2 ng/g). Brodifacoum concentrations in blood were determined weekly over the course of the study. Clotting times, as measured by PT, between the control and brodifacoum groups were not significantly different at any of the timepoints through week 6 post toxicant exposure. Delayed type hypersensitivity tests were not significantly different between control and brodifacoum dosed groups in the first three time points tested. Completion of this investigation will assess gross impacts of environmentally realistic brodifacoum exposure on humoral and cell mediated immunity against foreign antigen exposures in domestic cats. Additional studies will need to be conducted to determine if non-target exposure to brodifacoum could increase susceptibility to potential pathogens. \n

An in silico modelling perspective to advance hazard assessment of aquatic ecotoxicology

335

Evaluation of currently available methods for determining log Kow values of surfactants

G. Hodges, Unilever Research / Safety and Environmental Assurance Centre; J. Adnett, Dow Chemical Company; B. Bossuyt, HUNTSMAN Europe bvba / PEHS; A. Bouvy, Cefic; C.V. Eadsforth, Shell International / Shell Health; M. Enrici, SOLVAY / HSE PRA PS; M. Geurts, Akzo Nobel N.V. / EET; D. Miller, Clariant GmbH; G. Oetter, BASF SE / Materials Physics and Analytics; P. Sun, The Procter & Gamble Co.; J. Venzmer, Evonik
The n-octanol/water partition coefficient (log Kow) is a key parameter in chemical environmental studies as it determines the environmental fate and bioavailability and thus toxicity of a compound. Due to their unique properties, measurement of log Kow values of surfactants is a technical challenge. The traditional 'shake-flask' method (OECD 107) is no longer considered appropriate. Here we compare log Kow values of surfactants were compared using a range of existing experimental and predictive methods which have been used by lead registrants in REACh phases 1 and 2. However, there are concerns that these methods have not been fully validated for surfactants and may not be applicable due to the specific phase behaviour of surfactants, leading to unreliable or unrealistic values. This is complicated by the fact that the solubility is not properly defined for surfactants since they will form a micellar phase above the Critical Micelle Concentration (CMC) up to relatively high concentrations. In the light of this, logKow values were generated for a select set of 12 surfactants. Side-by-side comparisons of values derived using different experimental methods compared against predicted values identified whether certain existing methods give similar results for the same surfactants and recommendations made.

336

New Mechanism of Action definitions based on Molecular Initiating Events and a classification algorithm based on calculated structure properties.

F. Bauer, P. Thomas, KREATiS; S. Neunlist, S. Fouchard, Université de Haute-Alsace / Laboratoire de Chimie Organique et Bioorganique EA
A good understanding of Mechanisms of Action (MechoAs) and appropriate methods to determine them is crucial for the efficient prediction of ecotoxicity using *in silico* techniques. Different MechoAs will need different parameters or different coefficients to calculate toxicity values. To date, several classification methods, based on molecular structure analysis, exist to determine the Mode of Action (MoA) in aquatic species. The most commonly used one in regulatory ecotoxicology is the scheme proposed by Verhaar and co-workers (1992). The MoAs defined according to this scheme are based on chemical group reactivity and differences in logK_{OW} – logEC50 relationships. However, to be able to derive accurate predictions of modes or mechanisms of action only from structure, a classification is required that is based on Molecular Initiating Events leading to an adverse effect. So we defined a new set of MechoAs, partly based on the work of Russom and co-workers (1997). The approach used in Verhaar's classification algorithm has several limitations, and some classification errors were reported (Ellison *et al*., 2015). This classification algorithm is indeed based on a decision tree identifying 2D structural features that are recognised to lead to a certain MoA, limiting its Applicability Domain. In the present work, an approach to define MechoA for narcotics and beyond was applied using molecular modelling to obtain calculated molecular parameters depending on the 3D structure, such as E(LUMO) and qMaxH. A similar approach has already been implemented with success for a limited set of chemical families (Asadollahi-Baboli, 2012; Schultz *et al*., unpublished work). The results of this new algorithm coupled with the use of more pertinent MechoAs were compared with those obtained with Verhaar's scheme, as implemented in ToxTree software, using a comparison dataset taken from the literature (Ellison *et al*., 2015). With this new method applied to the validation set, we obtained 79% correct classifications, 11% misclassifications, 7% of the substances fell in a zone where two possible MechoAs couldn't be differentiated and the remaining 3% where out of the Applicability Domain of the algorithm. The same test applied to the Verhaar scheme with the same validation set obtained only 48% correct classification, 14% misclassifications and as much as 38% out of the Applicability Domain. Thus work on this new method will be continued.

337

Fragment Model to Predict the Rate of Hydrolysis for Organic Compounds

R. Kühne, R. Ebert, G. Schüürmann, Helmholtz centre for environmental research - UFZ / Department of Ecological Chemistry
Hydrolysis as one of the key degradation processes in the environment is considered to be important for a number of classes of organic compounds as carboxylic acid esters and amides, anhydrides, epoxides, isocyanates and isothiocyanates, carbamates, phosphate and thiophosphate esters, alkoxysilanes and halosilanes, and halogenated hydrocarbons. However, the number of available experimental data is rather limited. Computer models are a promising alternative to overcome respective data gaps. The overall hydrolysis is a combination of the reaction with neutral water molecules and acid and base catalysed degradation reactions. These processes will take place to a different degree. Since the acid and base catalysed degradation depends on the pH, the role of the individual processes and thus the overall rate depend on the pH of the aquatic environment. A feasible model approach is to express this rather complex system of reactions in terms of simple pseudo-first-order kinetics. The reaction with neutral water is directly addressed by a pseudo-first-order rate that is a constant for a given chemical and temperature and independent of the pH. Acid and base rates are primarily derived as pH-independent second-order rate constant and then transformed into pseudo-first-order rates by application to a fixed pH and thus to given H^+ or OH^-

concentrations. For the fixed pH the overall rate then can be calculated from the combination of the individual rates. In the presented study, three independent fragment models are being developed for the individual pH-independent rate constants, and the overall rate constants are obtained by putting them together for a particular pH then. The model is implemented and will be publically available after its finalisation in the OSIRIS edition of the software system ChemProp (UFZ Dpt. Ecological Chemistry 2015. ChemProp 6.3 http://www.ufz.de/index.php?en=6738). The training set consists of about 2200 compounds of all considerably hydrolysing compound classes. For ca. 670 substances, rates of the neutral reaction are available, and for the acid and base catalysed reaction there are data for 750 and 1280 chemicals. The models comprise ca. 75, 85, and 125 structural fragments for the estimation of the neutral, acidic, and basic rate. The performance with respect to the overall rate is ca. 0.9 (squared correlation coefficient of regression). The reliability of the model and the comparison to existing approaches will be discussed.

338

Development of parameters to predict hydrophobicity and sorption of non-ionic and anionic surfactants

J. Haftka, Utrecht University / Institute for Risk Assessment Sciences; J. Hammer, University of Utrecht / IRAS; P. de Voogt, University of Amsterdam / IBED; J. Hermens, Utrecht University / Institute for Risk Assessment Sciences

Octanol-water partition coefficients (K_{ow}) are often used in environmental risk assessment as a measure for hydrophobicity of organic contaminants to predict bioaccumulation, toxicity, and sorption to soil. The K_{ow} value is therefore an important parameter in predictive modelling of environmental fate and exposure of organic contaminants. However, application of the K_{ow} value as a parameter in predictive models for surfactants becomes problematic because of the amphiphilic nature of surfactants. More knowledge about the environmental behaviour of ionized and surface-active substances is therefore required to expand the chemical applicability domain of the currently used predictive models. Sorption of surfactants to polymer-coated fibres can be used as a measure of hydrophobicity. In addition, retention on stationary phases used in liquid chromatography (e.g., C_{18}, HILIC or ion-exchange phases) can be used as a probe to simulate sorptive interactions of surfactants with relevant environmental sorption phases (e.g., membrane lipids, organic matter, etcetera). The applicability of polymer phases and selected stationary phases to determine the hydrophobicity of non-ionic and anionic surfactants and to predict their bioaccumulation in aquatic organisms will be explored in this study based on literature and experimental data from different surfactant groups. The possibility of using such methods as a measure of hydrophobicity will have important consequences for the regulatory evaluation of surfactants within REACH and OSPAR. Results from this study show that fibre-water sorption coefficients and capacity factors on a C_{18} phase show great promise for the prediction of hydrophobicity of non-ionic and anionic surfactants. These values that reflect differences in hydrophobicity can be correlated with available data of bioaccumulation, toxicity or sorption. However, a single parameter or a single polymer or hydrophobic phase will not be sufficient in predictive modeling of sorption phenomena of surfactants to environmental phases. Likely, a series of phases are needed that correspond with specific types of interaction.

339

Replacing Fish Acute Toxicity Tests by QSAR Predictions: How much is realistic?

M. Nendza, Analytisches Laboratorium AL-Luhnstedt; M. Müller, A. Wenzel, Fraunhofer-Institute for Molecular Biology and Applied Ecology

Alternative methods like QSARs (quantitative structure-activity relationships) can replace some (eco)toxicity testing in regulatory contexts (e.g. REACH). Complete substitution of in vivo animal tests by in silico methods is, however, not realistic. Reliable QSAR predictions from the octanol/water partition coefficient (log K_{ow}) are possible only for certain classes of chemicals, the so-called baseline toxicants. Other chemicals that may reveal excess toxicity and/or act by specific modes of action (MOA) require further assessments. For fish acute toxicity, we derived a scheme to group chemicals as either baseline toxicants (= predictable by QSARs) or as potential excess toxicants (= not predictable by baseline QSARs). This scheme was tested with a new data set obtained with diverse fish species. Only for baseline toxicants, it is possible to predict the fish acute toxicity with sufficient accuracy from log K_{ow} and, hence, valid QSARs can replace in vivo testing. In contrast, excess toxicants and chemicals not reliably classified as baseline toxicants, require further in silico, in vitro or in vivo assessments. The stepwise approach identifies baseline toxicants (true negatives) in a precautionary way, not ignoring possible excess toxicants (true positives). At the same time, we tolerate a certain fraction of false positives, i.e. baseline toxicants without specific effects that may be tested instead of predicted. The way to replace many fish acute toxicity tests by QSAR predictions takes 3 steps: First, we use a classification scheme to discriminate between baseline and excess toxicants. Second, we apply high quality QSARs that meet the requirements for regulatory acceptance to replace in vivo fish acute toxicity tests for baseline toxicants with QSAR predictions. Third, the remaining chemicals, i.e. excess toxicants and chemicals not reliably classified as baseline toxicants, have to be assessed by further in silico, in vitro or in vivo methods. Application of the classification scheme to identify potential baseline toxicants to a new heterogeneous data set obtained with diverse fish species results in about 50% baseline toxicants, almost 30% excess toxicants and nearly 20% compounds not classified. Thus, we can conclude that replacing at least 50% of the fish acute toxicity tests by QSAR predictions is realistic.

340

Can we venture beyond experimental limits using HA-QSAR methodology?

P. Bicherel, P. Thomas, KREATiS

In aquatic ecotoxicology water solubility is considered a key parameter since it provides an indication of how much of a substance can be available for uptake by organisms. In general ecotoxicity of very hydrophobic substances are difficult to measure. They are likely to not have reached equilibrium within the experiment's duration and it is often technically difficult to achieve accurate concentration measurements. On the contrary no quantitative method is available to assess the miscibility of very water soluble substances. QSAR/QSPR modelling is a semi-empiric approach based on measured data. Their applicability domain tends to be limited by the extreme values in the available dataset. In this presentation we consider whether extrapolations beyond the data boundaries can be justified for both miscible and very hydrophobic substances using High-Accuracy QSAR models. On the hand, for "miscible substances" without any experimental quantification of the solubility, the water solubility values predicted by the HA-QSAR model are completely in agreement with the ecotoxicity values even if they cannot be compared to experimental water solubility. At the other end of the scale predicted QSAR values cannot be extrapolated beyond a recognised solubility/log K_{OW} cut-off value since acute tests are too short to reach equilibrium for very hydrophobic substances. Thus, for certain QSAR models, it is not the availability of the extreme datapoints in the dataset that determine the applicability domain, but other factors such as equilibrium with the test duration that will determine whether a substance endpoint value can be accurately predicted or not.

Mechanistic effect modelling for risk assessment: state of the art, applications, use in a regulatory context and future directions (I)

341

Selecting mechanistic effect models for environmental risk assessment; the link with protection goals and test protocols

T. Jager, DEBtox Research / Dept of Theoretical Biology

Virtually all frameworks for environmental risk assessment assess risks by combining the results from an exposure and an effects assessment. Estimation of exposure concentrations relies heavily on mechanistic fate models, but for the effects side, in contrast, focus lies with toxicity testing and descriptive statistical treatment of data. Mechanistic effect models do exist, however, and are gaining increasing interest in a regulatory context. A wide range of effect models exists at different levels of biological organisation (individual, population, community). These models differ in their degree of complexity, in their underlying assumptions about the biological and toxicological reality, in their 'quality' (as assessed from a good-modelling perspective), and in their data requirements, making it impossible to see the wood for the trees. The selection of the most appropriate models cannot be performed in isolation. Model selection is best viewed in conjunction with two other issues: the protection goals and the test protocols. The protection goals, when explicitly formulated, will make it easy to select (or develop) useful models. And subsequently, the useful models should guide the most efficient design for toxicity testing. At this moment, the linkage between these three components (protection goal, model selection and test protocols) is rather chaotic. Protection goals defined in risk assessment regulations are too vague to be of much guidance, models are often developed by modellers out of scientific interest, and existing test protocols are generally quite useless to support parameterisation of mechanistic models. For these reasons, environmental risk assessments needs a more ambitious agenda to redesign the effects assessment, and that requires an integrated evaluation of the three main issues. Model selection cannot be performed by only considering the 'quality' of the models. Instead of focussing too hard on model 'quality', we need to consider that the task of model selection (or development of novel models) is intricately linked to the regulatory protection goals and to the process of designing test protocols. In this contribution, I will provide several example cases to demonstrate how these linkages might work out. I hope that this contribution can help to streamline the fruitful integration of mechanistic modelling into a regulatory setting.

342

Optimizing experimental design for calibration of GUTS models

S. Charles, University Lyon 1 / Laboratory of Biometry and Evolutionnary Biology; C. Albert, Eawag Swiss Federal Institute of Aquatic Science and Technology; B. Goussen, University of York / Environment Department; T. Jager, DEBtox Research / Dept of Theoretical Biology; S. Vogel, Eawag Swiss Federal Institute of Aquatic Science and Technology; R. Ashauer, University of York / Environment

The General Unified Threshold model of Survival (GUTS) provides a theoretical framework for analysing stressor effects on survival over time through consistent model equations based on different assumptions about the stressor quantification, the compensatory processes and the nature of the death process. In ecotoxicology, stressors are toxicants characterised by a dose metric, e.g. the concentration in the medium surrounding an organism or inside the organism, or by the damage quantity they cause. The key GUTS feature is that mortality is estimated when the dose metric exceeds a certain threshold. Several GUTS flavours can be derived according to the assumption underlying the death process: (i) the threshold is distributed within a population, and when exceeded, the individual dies (individual tolerance, IT); (ii) there is one common threshold for all individuals, and when exceeded, the probability to die increases (stochastic death, SD); (iii) a unification of both previous assumptions (GUTS proper). While more realistic, GUTS proper requires the estimation of one additional parameter. Because environmental risk assessment of chemicals depends on robust estimates of GUTS parameters, we investigated parameter identification for GUTS proper, in relation to the experimental design of 'short-term' laboratory bioassays. In practice, standard survival datasets generally do not contain enough information to estimate all parameters of GUTS proper with sufficient precision. This is because a large number of individuals is required to provide strong information on probabilistic events. Hence, based on simulated datasets we identify appropriate experimental designs suitable to estimate all parameters of GUTS proper with the best possible precision. We show that datasets with a high number of animals per treatment allow for parameter estimation of GUTS proper with reasonable accuracy and precision. Moreover, increasing the number of animals or the duration of the experiment substantially reduce the uncertainty around the median value of the threshold. Nevertheless, general statements about optimisation for any chemical, any species, any test duration and/or any exposure concentration profile remain difficult. As take-home message, to the extent possible, we recommend not to use fixed experimental set-up for GUTS analyses, but rather tailor dedicated designs according to the chemical, the species and/or the research/regulatory question at hand.

343
Validation status of TKTD models: predictions of survival after time-variable exposure to pesticides match observations, but not all details
A. Focks, Alterra Wageningen University and Research Centre / Environmental Risk Assessment Team
TK/TD models are supposed to deliver relevant information for environmental risk assessment of pesticides, especially for the extrapolation from toxicity observed under constant laboratory conditions to survival under time-variable exposure, as expected for realistic application scenarios. TK/TD models from the GUTS framework describe the expected survival for a number of individuals being exposed to chemical concentrations over time. These models are structurally simple and consist of three or four equations for all species, and species- and compound-specific information is captured by the model parameters. Standard acute toxicity test results are often the only data being available for model parameterisation and can be used to parameterize the individual tolerance and the stochastic death survival submodels, using scaled internal concentrations as dose metric. For an application in risk assessment, it is required to check the quality of model predictions, or, with other words, to validate parameterised models for specific combinations of compounds and species. This study presents validation results for TK/TD models for some sets of species and compounds, including the neonicotinoids imidacloprid, thiamethoxam and thiacloprid, the benzimidazole fungicide carbendazim, the pyrethroid insecticide cypermethrin, and the organophosphate insecticide and acetylcholine esterase inhibitors chlorpyrifos, dimethoate and malathion, using models that were parameterised on standard acute data and using observed survival of individuals under time-variable exposure as validation data sets. The objective was to give an overview of the validation status of GUTS models and to analyse the validation results for patterns of prediction qualities across different compound classes and species. In short, from the current results no obvious patterns in prediction qualities appear that relate to specific models, species or compounds. Despite the goodness of fit of the temporal dynamics is of limited quality for some datasets, the match of observed and predicted survival at the end of the experiments is acceptable (shown in presentation). This observation indicates that TK/TD models can be used to reduce uncertainties in risk calculations for time-variable exposure time series, as compared to ratio-based methods. Subtle patterns in survival can possibly only be predicted when the model is being calibrated on survival data obtained from more complex exposure scenarios

344
Exposure specific species sensitivity - a toxicokinetic-toxicodynamic approach
A. Gergs, gaiac - Research Institute for Ecosystem Analysis and Assessment / Department of Environmental Social and Spatial Change; R. Ashauer, University of York / Environment; S. Augustine, Akvaplan-niva; A. Nyman, Euroean Chemicals Agency; V. Poulsen, ANSES / French Agency for Food Environmental and Occupational Health and Safety; T. Preuss, Bayer CropScience / Environmental Modelling; P. van den Brink, Alterra and Wageningen University / Aquatic Ecology and Water Quality Management Group; K. Veltman, University of Michigan / Department of Environmental Health Sciences; E. Zimmer, IBACON GmbH
Currently in higher tier environmental risk assessment of chemicals, species sensitivity distributions (SSD) are used to describe and to quantify differences in sensitivity among species. When available for multiple species, no-observed-effect-concentrations (NOECs) or ECx, (representing x% of an affected population) usually derived from acute and chronic toxicity tests under constant exposure, are being used to calculate SSDs. In turn, these SSDs are used to extract 'safe' community effect thresholds in the form of an HC5, i.e. the concentration at which 5% of the species are affected. In current ERA practice, the ratio of effect measures and exposure, such as the maximum predicted exposure concentration (PECmax) or the time weighted average (TWA), are being employed to characterize risk ignoring that, depending on environmental conditions, the exposure concentrations are highly variable in space and time. Mechanistic models, such as the General Unified Treshold model of Survival (GUTS), take the process leading to an effect into account and can explicitly cope with time variable exposure. We present the outcome of a GUTS workshop held in March 2015 where species sensitivity distributions under time variable exposure have been studied. Our results point towards an unrecognized problem with the widely used SSDs and HC5 values: they could depend on the exposure pattern and differ a lot for exposures with the same time weighted average concentration but different temporal profiles. By using GUTS to analyze and compare species sensitivities, we can overcome the dependence of time and exposure patterns, and extrapolate toxicity to other exposure scenarios. Furthermore, we can develop a more thorough understanding of the underlying toxicity mechanisms by quantifying organism internal toxicity thresholds in conjunction with compensating processes.

345
How to map ecological risk assessments of chemicals
B. Goussen, University of York / Environment Department; C. Rendal, A. Franco, O. Price, Unilever / Safety and Environmental Assurance Centre SEAC; R. Ashauer, University of York / Environment
The lack of ecological realism is widely recognised as a limitation in current prospective chemical risk assessment, as is the failure of making variability explicit and transparent. The integration of ecological scenarios with chemical effect models to achieve quantitative ERA promises to increase ecological relevance. Probabilistic environmental risk assessment (PERA) has been suggested as a way to account for spatial, temporal, and environmental variability. Probabilistic plots area new way of presenting ecotoxicological data whilst accounting also for ecologically relevant parameters. They provide an indication of the maximum population-relevant impact of an effect of interest (e.g. biomass reduction) and the prevalence of this impact. Essentially they answer two related questions: How strong is the effect? In how many locations will we see the effect? We discuss some of the challenges and opportunities involved in bringing these new concepts into everyday risk assessment for down-the-drain chemicals. One of the key questions revolves around understanding the protection goal for anthropogenic stressors in specific ecological scenarios, and indeed whether certain scenarios require specific modified protection goals. Once the specific protection goal has been established, a metric to suit both the specific ecological scenario and protection goal needs to be defined and agreed. The selection of this endpoint must be carefully considered as different options will lead to different interpretation. We present a framework to integrate probabilistic approaches with mechanistic effect models to assess variable chemical and environmental scenarios. We present a hypothetical case study risk assessment for an ingredient used universally in all laundry products across Europe and illustrate the potential benefits of the framework. To do so, we use an individual based model integrating a dynamic energy budget model to assess the potential impact of chemicals associated with local environmental characteristics. We then map the outcomes based on probabilistic plots and on potential policy makers' decisions of the maximal ecologically acceptable impact and the maximal prevalence of this impact. This new framework has the potential to better present ecologically relevant risk by using integrated biological endpoints and to aid more transparent risk communication.

Application of a coordinated OMICS research program and data into regulatory frameworks: case-studies and perspectives

346
SETAC Global Advisory Group OMICS: Cutting-edge science to solve real world problems
A. Biales, U.S. EPA / National Exposure Research Laboratory; B. Campos, IDAEA-CSIC / Environmental Chemistry; J. Colbourne, University of Birmingham / Biosciences College of Life and Environmental Sciences; D. Vidal-Dorsch, VDA LCS / Toxicology
Governments around the world are passing new legislation to regulate chemical substances considering their potential impacts on both human and environmental health. These are critical and complex rules, designed to better ensure public

safety, a healthy environment and functioning ecosystems. However, there are huge scientific and logistical constraints in determining risks for an ever-increasing number and diversity of products introduced to markets. Standard operating procedures for toxicity testing are typically prescriptive and have not fundamentally changed, being too expensive and time consuming to keep pace with requirements.To fully implement these policy directives, we require equally novel, revolutionary and coordinated scientific approaches that are rapid, cost effective, and consistent with global ethical standards for the treatment of animals.A proposed solution is to apply OMICS approaches. Key questions that arise include the reliability and cost of these and the extent to which OMICs measurements can be tied to mechanisms of toxicity and adverse outcome pathways.Following several activities/discussions organized within SETAC in the last decade, the Global Advisory Group OMICs (**OMICs AG**) was recently being established. Here, we will be rolling out the mission, objectives and goals we propose to reach and how we plan to achieve them.**The OMICs AG** will provide a platform for discussion, and a means of raising awareness among stakeholders. To do this, we plan to coordinate dialogue in the community in order to further improve and standardize the information generated by scientists making it usable by decision makers, facilitating the innovation of ethical and cost-effective testing procedures. In the short and long term, this AG wants to be a key player in a global dialog, cementing a leading role for SETAC scientists while fostering ongoing discussions about how to proceed on a scientific level to maximize gains for industry and policy makers around the world.We want to take this opportunity to invite the community to join this discussion and contribute to a better environmental and human protection without jeopardizing our need for development and industry high rate of “responsible innovation”. We believe that only an open and honest dialogue among environmental risk assessors, academia, industry, regulators and legislators coupled with shared understanding of each other needs will be able to bring the environmental protection to a good point.

Molecular toxicology approaches to address the adverse outcome pathway for narcosis toxicity using Caenorhabditis elegans and the RTgill cell line as model systems

E.K. Brockmeier, University of Liverpool / Functional and Comparative Genomics; P. Antczak, University of Liverpool / Institute of Integrative Biology; G. Hodges, E. Butler, C. Rendal, Unilever / Safety and Environmental Assurance Centre SEAC; S. Gutsell, Unilever / SEAC; F. Falciani, University of Liverpool / Institute of Integrative Biology

Narcosis, or baseline toxicity, is a toxic mode of action predicted by QSAR analysis to occur in over 70% of industrial chemicals. However, there is currently no clear understanding of the mechanism of toxicity for these types of chemical stressors. Hypotheses include impacts on the electron transport chain, impacts on calcium signaling via the sarco/endoplasmic reticulum calcium ATPase, and an overlap with the mechanism of analgesic chemicals, which also act via a reversible and membrane-based mechanism. While our group has developed insights into potential genes and pathways of interest using computational biology approaches, we are also directly analyzing physiological responses. The objective of this project is to use *C. elegans* as a model organism for evaluating responses to narcosis stressors on a non-transcriptional level. Based on results from our transcriptomics experiments, we hypothesize that genes related to collagen structure and oxidative phosphorylation may have a role in the toxic responses elicited during narcosis. To evaluate this hypothesis, we conducted follow-up experiments to validate the role of these genes and pathways in narcotic responses. We validated gene expression of the collagen protein gene col-19 in *C. elegans* as being differentially expressed between polar and non-polar narcotics (one-way ANOVA, $p < 0.0001$). The role of this gene in narcosis toxicity responses (e.g. LC50) will be assessed using RNA interference (RNAi) approaches, where col-19 will be selectively knocked out followed by exposure to a panel of polar and non-polar narcotic chemicals. Based on results collected from a separate study in *Daphnia magna*, we are also using this approach to address the role of the *C. elegans* calcium ATPase (sca-1) by knocking down the function of this gene and comparing LC50 responses. We also directly address the impact of narcotic exposure on calcium signaling and oxidative phosphorylation using cell imaging and the Biosciences XF24 platforms respectively. These tools enable us to determine the physiological impacts of narcotic exposure. These physiological data will be linked to our transcriptomics and metabolomics data sets, as well as with parallel studies using the *in vitro* model RTgill cell line, in order to develop a robust adverse outcome pathway for narcosis toxicity and for incorporating this information into improved screening and assessment of chemical risk for this class of compounds.

348

Network analysis of gene expression profiles identifies gene networks driving changes in reproduction: a case study in Daphnia exposed to different binary mixtures.

J. Asselman, Ghent University / Laboratory for Environmental Toxicology and Aquatic Ecology GhEnToxLab unit; M. Pfrender, University of Notre Dame / Biological Sciences; J.A. Lopez, University of Notre Dame / Department of Biological Sciences; K. De Schamphelaere, Ghent University (UGent) / Laboratory for Environmental Toxicology and Aquatic Ecology GhEnToxLab unit

Over the last decade, molecular technologies have evolved into robust high throughput platforms yet implementation of these technologies in ecotoxicology and risk assessments remains difficult and is limited to small datasets. As a result, knowledge of stress responses and mechanisms of toxicity across stressors and particularly mixtures remains limited. Here, we report the use of high throughput microarrays to study 48 binary mixture combinations of cyanobacterial stress and insecticide contamination to *Daphnia*. We identified gene networks that correlated significantly with changes in reproduction in *D. pulex*. These gene networks were diverse in size and function and could be represented by a small subset of 10 core or hub genes. This suggests that (1) only a limited number of genes is driving expression patterns that correlate with reproduction at the organismal level and (2) these limited subset of genes can be divided into several independent gene networks. The results highlight the potential of network analysis in combination with high throughput molecular data for environmental risk assessment.

349

Developmental neurotoxicity assessment of chemical exposure in children: weight of evidence approach using in vivo behaviour, metabolomic and proteomic studies

P. Leonards, VU University, Institute for Environmental Studies / Institute for Environmental Studies IVM; S. Tufi, VU University Amsterdam Institute for Environmental Studies; M. Llansola, B. Gomez-Gimenez, Centro de Investigación Principe Felipe; S. Jung, Proteome Sciences; V. Felipo, Centro de Investigación Principe Felipe

Worldwide, serious concern has arisen about the increased incidence of learning and developmental disorders in children. From a scientific point of view, there is no doubt that exposure to neurotoxic chemicals during early brain development can adversely affect learning and development. Various recent epidemiological studies have indicated that exposure to low doses of environmental biologically active contaminants (e.g. pesticides) during human development can have deleterious effects on cognitive development in childhood. The European commission-funded project DENAMIC "Developmental Neurotoxicity Assessment of Mixtures in Children" investigates neurotoxic effects (e.g. learning and developmental disorders) of low-concentration mixtures of pesticides and a number of common environmental pollutants in children. We focus on (subclinical) effects on learning (cognitive skills) and developmental disorders in children (e.g. ADHD, autism spectrum disorders and anxiety disorders). The aims are to develop better and sophisticated tools, procedures and testing methods to screen compounds for (developmental) neurotoxicity, and to improve our understanding of chemical exposures and the observed effects (www.denamic-project.eu). As part of the project, a new alternative assessment strategy based on a combination of *in vitro, in vivo* assays, omics, and human exposure assessment is under development in order to prioritize compounds, and to further investigate the pathways and mechanism involved in disorders and diseases. The final aim of DENAMIC is to reduce effects of environmental contamination on learning and developmental disorders in children. In the current study, a weight of evidence approach is followed to improve our understanding of the underlying molecular mechanisms of observed effects on behaviour and cognitive function of various pesticide exposure in rats using metabolomics and proteomic studies.

Potential and Limitations of Comparative Genomics for Predicting Pharmacological Effects of Pharmaceuticals in Fish

L. Gunnarsson, University of Exeter / Biosciences; E. Kristiansson, Chalmers University of Technology / Department of Mathematical Statistics; T. Österlund, Chalmers University of Technology / Mathematical Sciences; S. Owen, AstraZeneca / Safety Health Environment; J. Snape, AstraZeneca UK Ltd. / AstraZeneca Global Environment; C. Tyler, Biosciences College of Life and Environmental Sciences

Identification of orthologous genes is an important step in the assessment of evolutionary conserved functions. Within the field of (eco)toxicology, information regarding orthologous relationship holds promise to predict conserved, chemical induced, mode of action (MoA) across species and thus help to guide the selection of appropriate test species for further testing. We have started to explore the potential and limitations of such an approach by analysing orthologous relationships between human drug targets (466) and corresponding proteins in more than 40 vertebrate genomes, including 13 species of fish (11 teleosts). We have previously shown that ~ 85% of the human drug targets are conserved in fish. A growing number of publications comparing pharmacological effects and therapeutic concentrations in humans to internal concentrations and pharmacological effects in fish provide support for ortholog detection as a strategy to inform extrapolations of effect data across species. It is more challenging however to identify species and taxa that are lacking orthologs and/or effects. To address this question we focused our predictions on the identification of drugs that are lacking pharmacological effects in fish. We have analysed predictions of orthologous relationships from two databases (Ensembl Compara and Inparanoid), which uses different strategies for the predictions. Only three of 976 drugs lack orthologs to all pharmacological targets in all fish studied. In the case of Amiloride, despite the absence of the sequence targets, published studies show it can induce specific, pharmacologically related effects in fish (inhibition of sodium transport), albeit at concentrations several orders of magnitude higher than in humans. This effect (in fish) is mediated via conserved off-targets. The example re-enforces the need to consider effective concentrations and off-target effects in API assessments. The results of the ortholog detection also predict that 84 drugs (46 targets) are lacking all pharmacological targets in at least one but not all species of fish. Additional data, supporting these potential gene losses were however available only for two targets. In conclusion, ortholog detection holds good promise for identification of conserved chemical MoA across species but the lack of predicted orthologous targets doesn't rule out biological effects for drugs, and thus findings from such an approach need to be interpreted with caution.

Toxicity testing and transcriptomics with Daphnia magna and application to Danube risk assessment in SOLUTIONS
T. Williams, University of Birmingham / School of Biosciences; M. Hockedy, The University of Birmingham / Biosciences; P. Antczak, University of Liverpool; T. Schulze, Helmholtz centre for environmental research - UFZ / EffectDirected Analysis; M.R. Viant, University of Birmingham / School of Biosciences; J.K. Colbourne, The University of Birmingham / Biosciences
The SOLUTIONS project aims to find new and improved tools, models, and methods to support decisions in European environmental and water policy. In addition to a wide selection of bioassays, transcriptomics assays are being performed using Daphnia. Crucially, the extensive chemical and ecological characterisation of environmental sampling sites on European rivers presents the possibility of linking chemical data to adverse ecological outcome via biological responses following the AOP paradigm Large volume solid phase extraction (LV-SPE) was used to concetrate organic extracts from 1000 litres of surface water at 25 sampling sites on the Danube during the Joint Danube Survey 3 (JDS3) project and SOLUTIONS. Acute toxicity of the Danube LV-SPE samples to Daphnia was tested experimentally by a modified version of OECD Test No. 202[3]. Neonates from sublethal exposures were collected and frozen at -80C prior to RNA preparation and transcriptomics. Transcriptomics employed a novel 8x60k *Daphnia magna* Agilent oligonucleotide microarray design. From chemical data, PAHs (benzo(g,h,i)perylene, indeno(1,2,3-c,d) pyrene and fluoranthene) and the AChE inhibiting insecticide diazinon were predicted to pose the most risk of Daphnia acute toxicity, considering all Danube sites. Daphnia toxicity determined experimentally correlated positively with predicted toxicity ($r=0.49$; P-value < 0.05), although several outliers were noted. At the Novi Sad site toxicity at the effluent inflow was significantly higher ($P< 0.05$) than immediately upstream. Daphnia transcriptomic responses to the Danube environmental extracts provide data to characterise the similarities and differences between sites of different pollution profiles. Although there was a positive correlation between Daphnia toxicity predicted from chemical concentrations and those determined experimentally, several outliers showed that additional factors influence toxicity. These are likely to include chemicals not detected or considered in the analysis, or for which there is insufficient Daphnia toxicity data, as well as interaction between components of the mixtures. Detailed transcriptomic investigation of Daphnia responses to the different environmental extracts, in combination with chemical, ecological and other bioassay data, have the potential to reveal candidate compounds associated with deviation of toxicity from that predicted by risk assessment

Challenges in Environmental Assessment of Cosmetics and Personal Care Products

352
Regulation of cosmetic ingredients under REACH: Is it necessary? - A case study with 3-BC and 4-MBC
F. Kaßner, Umweltbundesamt / Federal Agency of Environment / IV Chemicals
Many active ingredients of cosmetic products can enter the environment during use and disposal. Special concern is arising from the group of commonly used UV filter substances in sunscreens and other cosmetic products since they enter surface water bodies directly via wash-off during use and without being processed within waste water treatment plants. The problem here is that the EU cosmetic regulation does not allow for higher tier testing using in vivo assays. Thus, PBT, vPvB and e.g. endocrine disruption, being the most critical hazards arising from chemicals from an environmental point of view, cannot be evaluated based on the data requirements under the cosmetic regulation. The presented case study should demonstrate, using the example of two camphor-based UV filter substances, how the identification of environmental risks and their management can be addressed under REACH. In this context a research project dealing with the relevance of potentially endocrine disrupting substances for regulation the uses and findings of 3-BC and 4-MBC in the environment were evaluated. Furthermore, a sound evaluation of the SVHC properties of both camphor substances is being performed under REACH aiming at identifying both UV filter chemicals as substances of very high concern for the environment. Finally, a risk management option analysis (RMO) is performed to identify the most adequate and effective risk reduction approach. Part of this evaluation is also a discussion of the substances within the ECHA expert groups (e.g. the Endocrine Disruptor Expert Group) and a public consultation of the outcome of the RMO analysis and the SVHC identification. This ensures a transparent process for all stakeholder groups being involved. The REACH framework provides useful tools to evaluate and to manage cosmetic ingredients of environmental relevance. Especially the option to request higher tier in vivo data under the substance evaluatiuon process within REACH, which is not possible under the EU cosmetic regulation, is of high relevance to clarify hazardous properties of very high concern (CMR, PBT, vPvB and e.g. endocrine disruption) of cosmetic ingredients. Thus, assessing cosmetic active ingredients under REACH can be an efficient approach to minimize their environmental and/or human health risks and be a potent driver for substituting critical chemicals in cosmetic consumer products.

353
UV-filters and musk from Personal care products in coastal regions : Seasonal and diurnal trend in mussels and seawater.
M. PICOT-GROZ, UFR Pharmacie Hydrosciences; H. FENET, Université de Montpellier - UMR 5569 Hydrosciences / UFR des Sciences Pharmaceutiques; M. MARTINEZ BUENO, Université de Montpellier - UMR 5569 Hydrosciences / Hydrosciences Montpellier; D. ROSAIN, Université de Montpellier - UMR 5569 Hydrosciences; E. Gomez, Université de Montpellier, Hydrosciences Montpellier UMR 5569 / Sc Environnement Sante Publique
UV-filters and musks fragrances have come into focus because these compounds are increasingly used in sunscreen products and in many products of daily use, such as cosmetics, skin creams, plastics or varnish. These compounds have gained increasing interest due to their occurrence in the environment and to their potential to cause endocrine disruption. UV-filters have been reported in coastal regions mainly due to recreational bathing activities, including both sea water (Sankoda et al. 2015) and marine mussels (Bachelot et al. 2012). The highest concentrations of UV filters in mussels were reported for two substances, ethylhexylmethoxycinnamate (EHMC) and octocrylene (OC) and occurred in sites with a strong touristic frequentation and a geomorphological conformation of the beach closed to the wide. In this context, the objectives of this work were three folds: firstly, a monitoring of the seasonal variations and diurnal trends of these emerging contaminants was conducted during the touristic period. Secondly, the relation between the concentration in water and in mussels was studied within one day for a better understanding of the temporal trends. Finally, the contribution of WWTP releases on coastal contamination was investigated. The extraction of mussel tissues was based on a QuEChERS procedure (Picot-Groz et al. 2014). Sea water was extracted with semi-preparative extraction (SPE) method. Analysis was performed with liquid chromatography coupled to high resolution mass spectrometry (LC-MS/MS) and gas chromatography-mass spectrometry (GC-MS/MS). The developed analytical method allowed to detect target compounds at low levels under 10 ng/g in marine mussels and under 1 ng/L in sea water samples. A seasonal variation of OC and EHMC was observed with the highest concentration in mussels reported in July while the strongest touristic pressure. The diurnal trend of UV filters was similar in sea water and in mussels. These results suggest a high bioconcentration potential in mussels, and probably a metabolism ability for these substances. This is in accordance with previous findings where mussels feed with contaminated phytoplankton bioaccumulated low UV-filter concentration (Gomez et al. 2012). One UV stabilizer (UVP) and one musk (galaxolide) occurred in mussels from a non protected area, indicating other inputs than bathing. The reason evoked is the arrival of WWTP rejects that do not allow a complete elimination of these compounds.

354
UV filters bioaccumulation. The need for metabolites inclusion when carrying out ERA
D. Molins Delgado, IDAEA-CSIC; F. Flores, S. Diaz-Cruz, IDAEA-CSIC / Environmental Chemistry; D. Barcelo, IIQAB-CSIC / Dept Environmental Chemistry
Environmental Risk Assessment (ERA) considers the impact on the environment caused by substances in daily use products, pesticides, etc. In addition to ERA, it is also wise to assess the risks posed to human and animal health by chemicals which may be present in the environment and consequently may enter the food chain. After use, personal care products (PCPs), may be absorbed by the body and excreted or washed off. PCPs and their metabolites enter the aquatic environment. There, they are partially eliminated in WWTPs and released to the water bodies through the effluents [1]. On the last ten years, the concern about the potential hazardous risk associated to them and their byproducts, that can be more persistent and toxic [2], has been on the rise. In this study we investigated the bioaccumulation potential of BP3, BP1, 4HB, 4DHB, OD-PABA, OC, EHMC in wild seafood of economic significance to provide data for a reliable ERA. In Brazilian fish samples gills, muscle and liver were analysed separately to estimate accumulation distribution among tissues. Pressurized liquid extraction (PLE) with in-cell purification of the samples was applied as extraction and purification technique. Extracts were analyzed by HPLC-MS/MS [3]. 4MBC was the most frequently compound observed in Perú samples and at the highest concentration

(549 ng/g dw in *Aulacomya ater*, "choro"). In the samples from Brazil, BP1 in the three fish tissues and OC in liver and gills were the predominant and most accumulated compounds. The occurrence of the metabolites, BP1, 4HB and 4DHB in the samples suggest that metabolites also accumulate in fish. Results revealed that UV filters were detected in all samples. Some of them are endocrine disrupting compounds that may cause negative effects on the reproduction and development of these species which may lead to their extinction and/or to affect humans through ingestion. Metabolites may be both excreted and bioaccumulated in the organisms. Thus, for a reliable ERA, metabolites should be considered. \n References [1] Nieto A, Borrull F, Marcé RM, Pocurull E. J. Eco-SUN for Eco-design of Sunscreen Using titanium dioxide Nanoparticles

J. Labille, CNRS; D. Slomberg, Labex Serenade/CEREGE/Aix-Marseille Université; D. Guerin, Laboratoires Biocos; J. Hubaud, Helioscience; S. Lehmann, ISTerre UJF; L. Hedouin, CNRS CRIOBE; V. Matranga, CNR IBIM; S. Motellier, CEA Liten; C. Santaella, CNRS/CEA/Aix-Marseille Université / Bioscience and biotechnology Institute of Aix Marseille; I. Capron, INRA BIA; A. Glaser, Novancia Business School; P. Hennebert, INERIS; C. de Garidel-Thoron, CNRS AMU CEREGE

Among cosmetics and personal care products, sunscreen products are of emerging concern regarding both human and environmental health. The fate and impact of mineral nanoparticulate UV-blockers, such as TiO_2 nanomaterials, is under consideration from a regulatory perspective due to their potential impact. Once leaving the skin either through bathing or everyday usage and cleaning, the nanomaterials contained in the sunscreen can be released into rivers, lakes, sea shores, and/or sewage treatment plants. The nanomaterial behaviour, fate and impact in these different systems is largely determined by its surface properties, (e.g. the nanomaterial coating type) and lifetime. Here we present the first result of the Eco-SUN research program aimed at developing the eco-design of sunscreens through the minimization of risks associated with nanomaterials incorporated into the formulation. Different stages of the cream lifecycle are considered from its manufacture to its end of life, through its use by the consumer and its impact on the exposed environments. Reducing the potential release and / or toxicity of the nanomaterial from the cream is a decisive criterion for its eco-design. Different relevant TiO_2 UV-blockers have been selected to integrate a typical o/w formulation as case studies. The resulting sunscreen were characterised in terms of nanomaterial localisation, sun protection factor and photo-passivation. The risk for the consumer by dermal exposure was assessed using skin biopsies. Inflammation and skin penetration were evaluated. The risk for the aquatic environment directly expose was assessed both in terms of exposure and hazard. The release of nanomaterials from the sunscreen upon normal usage was studied in laboratory through simulated aging procedure. Two biological models, sea urchin and coral colonies, were selected as relevant endpoints to assess the marine ecotoxicity of the byproducts formed. Finally, the risk related to the end of life of the sunscreen through the removal with cleaning water followed by drainage to sewage treatment plants was evaluated by considering two opposite fate scenarios: (i) nanomaterial concentration in sewadge sludge later spread as fertilizer in agriculture, and (ii) nanomaterial suspension maintained in the treated water and released in river water. Thus, fate and impact in soil and river ecosystems were also studied.

356

Benthic Invertebrate Exposure and Body Burden Analysis for cVMS Materials - A Probabilistic Risk Assessment Approach

K.B. Woodburn, Dow Corning Corporation / HES; D.E. Powell, Dow Corning Corporation / Environmental Sciences; J. Kim, Dow Corning Corporation / Health and Environmental Sciences

Lipophilic chemicals, such as the cyclic volatile methylsiloxanes (cVMS) octamethylcyclotetrasiloxane (D4), decamethylcyclopentasiloxane (D5), and dodecamethylcyclohexasiloxane (D6), adsorb extensively to particles and surfaces in aqueous systems, making sediments the predominate repository when performing risk assessment evaluations. A widely accepted step for estimating the possible risk posed by such chemicals to sediment-dwelling species is to compare the observed sediment concentration with either published ecotoxicity guidelines or to chronic no-observed effect concentrations (NOECs) from toxicity testing with benthic invertebrates. The objective of this work was to compare field exposure sediment and biota levels of D4, D5, and D6 to chronic benthic invertebrate NOEC values, using a probabilistic risk assessment (PRA) approach and Monte-Carlo simulations to estimate the likelihood of exposure/toxicity overlap and to analyze the uncertainties associated with the risk assessment. For the three cVMS materials, no overlap of sediment exposure concentrations and chronic NOEC values was noted, with exposure distribution probabilities ranging from 95% to 99% and with chronic NOEC extrapolated probabilities of 1 to 5%. PRA successfully described the overlap of sediment exposure and chronic benthic NOEC distribution datasets for the cVMS materials. The use of Monte-Carlo analysis yielded descriptions of the probability of overlap of exposure and chronic NOEC, i.e., a quantitative description of the risk posed by these materials to benthic invertebrate organisms/populations. Using both sediment OC-based and lipid tissue-based analyses, the cumulative probability of exceedence of chronic NOEC levels for tested benthic invertebrate species is

357

Towards A New Method for Performing Environmental Risk of Complex Substances (CRANCS).

P. Thomas, CEHTRA SAS / Ecotoxicology and Risk Assessment; P. Remuzat, CEHTRA SAS; S. Betat, LPL; N. DELPIT, Laboratoires des Pyrénées et des Landes; B. Madru, LPL; P. Bicherel, KREATiS

Complex mixtures pose a significant problem for environmental risk assessors in Europe as guidance is unclear how to deal with input data. Aquatic ecotoxicity data can be generated using the Water Accommodated Fraction (WAF) method but derivation of PNECs in other compartments is not simple. Complex mixtures deposited into receiving water will differ in partitioning between the aquatic and sediment compartments, leading to a different constituent profile from the original mixture. The objective of the "Compartmentalised Risk Assessment for Natural Complex Substances" (CRANCS) project is to develop a predictive method for environmental risk assessment in aquatic medium for Complex Substances, notably essential oils. Concentrations of the constituents of known mixtures will be spiked to characterised sediment-water systems and measured concentrations of each constituent will be compared to those calculated using standard partitioning methods. Alternative partitioning calculations may be developed to quantify the partitioning of constituents between aqueous phase and sediment phase. This information will be used to define the PECaquatic and PECsediment. It is expected that the pelagic and sediment compartments will contain different mixtures (sub-mixtures) from each other and from the original complex substance. The spiked compartments will be tested for the influence these mixtures have on ecotoxicity, and a risk assessment will be carried out in both compartments: pelagic (water) *versus* benthic (sediments) at equilibrium using the PECs and acute and chronic aquatic toxicity data. The results will be compared to approaches currently used for estimating risk based on the original complex substance. The experimental phase will be performed on two complex mixtures (one prepared specifically for this study, containing not readily biodegradable, stable substances and a second one on a known NCS). The modellers will simulate the results *in silico* using the WAF mixture calculation on each sub-mixture (pelagic and sediment). An attempt will be made to calculate the sediment WAF validated by the experimental results. Ultimately it is hoped that the model can used in future risk assessments to accurately predict the ecotoxicity of NCS in both the water and sediment phases. This would significantly reduce the amount of experimentation necessary and should also be considerably more precise than the current risk assessment methods available for complex substances.

Endocrine Disruptors: Exposure, Hazard & Risk Assessment (I)

358

SETAC Pellston WorkshopTM: Environmental hazard and risk assessment approaches for endocrine-active chemicals (EHRA): developing technical guidance based on case studies to support decision making.

I. Sutherland, Department for Environmental Food & Rural Affairs / Chemicals Emerging Technologies; A. Leopold, Independent Consultant/ Researcher / Wildlife International Ltd.; G.T. Ankley, U.S. EPA / National Health and Environmental Effects Research Laboratory; M. Galay-Burgos, ECETOC; P.D. Guiney, Retired- S C Johnson & Son, Inc / Molecular and Environmental Toxicology Center; H. Holbech, University of Southern Denmark / Department of Biology; T. Iguchi, National Institutes of Basic Biology; K.A. Kidd, University of New Brunswick; A. Kumar, CSIRO / Center for Environmental Contaminants Research; P. Matthiessen, Independent Consultant; E.M. Mihaich, ER2; L.S. Ortego, Bayer CropScience / Environmental Toxicology and Risk Assessment; B.W. Vigon, SETAC; L. Weltje, BASF SE / Crop Protection Ecotoxicology; J. Wheeler, Dow Agrosciences

Suspected endocrine disrupting chemicals (EDCs) are now being evaluated by several regulatory authorities. A debate is in progress about whether or not EDCs can be adequately assessed by following the standard approach involving identification of intrinsic hazards, prediction of exposure and consequent calculation of risk, or if hazard alone should be used to decide if chemical registration can be permitted. Now that a number of mammalian, non-mammalian and *in vitro* test guidelines have been adopted by the Organisation for Economic Cooperation and Development (OECD) and the US Endocrine Disruptor Screening Program (EDSP) has generated significant data, the key challenge remains the integration of scientific evidence to support the hazard and risk assessment of chemicals with known or suspected endocrine activity. For this reason the SETAC-Pellston Workshop^{TM}Environmental Hazard and Risk Assessment Approaches for Endocrine-active Chemicals (EHRA) will be held from the 31st of January to the 5thof February 2016. Through the development of case studies it aims to develop tools that can be used by regulators and other decision makers involved in the assessment of chemicals with endocrine activity. 50 carefully selected scientists from a range of disciplines are working in case study groups each evaluating one of six chemicals known or suspected to have endocrine activity: 17 alpha ethinyloestradiol, trenbolone, perchlorate, propiconazole, vinclozolin and tributyltin. Per chemical approximately 150 publications and publicly available regulatory data have been selected for detailed evaluation. Following a Weight of Evidence assessment focused on endocrine activity, the main environmental hazards will be quantified looking at relevant taxa. Risk assessments for both endocrine-active and non-endocrine-active endpoints will be conducted. While going through this process the case study groups are asked to focus on a number of issues that cut across the different case studies and reflect the challenges that are faced when determining hazard and/or risk of endocrine active substances (EAS). The primary output of the workshop is the Synthesis Document which will be a technical, scientific guidance document primarily for regulators to support decision making in environmental hazard and risk assessment approaches for EAS. The presentation will discuss objectives, approach, output and regulatory impact of the workshop.

Endocrine disruptors - Regulatory decision making process at ECHA's Member State Committee

C. Ajao, ECHA-European Chemicals Agency; L. Wollenberger, European Chemicals Agency; K. Tyle, DK EPA / Chemicals; W. de Wolf, European Chemical Agency

REACH is an EU Regulation that requires 'standard information requirements' to be provided by manufacturers and importers of industrial chemicals in the EU. Under dossier evaluation, carried out by ECHA, the information in registration dossier is compared with the standard information requirements found in Annexes Vi to X of REACH. Further information may be requested if data gaps relevant for the safe use of the substance were identified. On the other hand, under substance evaluation, were Member State Competent Authorities (MSCAs) carry out an evaluation of a substance prioritised based on risk concerns and listed on the Community Rolling Action Plan (CoRAP), information that goes beyond the standard information requirements of REACH can be requested. Depending on the concern, more sophisticated experimental data or information on exposure or hazard (e.g. information related to Mode of Action like in relation to endocrine disruption or genotoxicity) may be requested for the priority substances. Some tests targeted for endocrine disruption are considered non-standard information requirements (e.g the fish Sexual Development Test or the Uterotrophic Assay in rats). ECHA's Member State Committee (MSC) is responsible under REACH for resolving divergent views among Member States and ECHA as regards the information Registrants and Downstream Users are required to generate to show that their substance can be used safely without harm to man or the environment. Furthermore, MSC can identify substances of very high concern (SVHC) for instance on the basis of CMR or PBT/vPvB properties. Endocrine disruptors may be identified on a case-by-case basis as SVHCs, where there is scientific evidence of probable serious effects to human health or the environment, which gives rise to equivalent level of concern to CMR or PBT/vPvB substances under Article 57 (f) of REACH. Two case studies to exemplify MSC's considerations and decision making process will be selected: one from a substance evaluation (benzophenone (BP)) and another case study from a SVHC identification (Bis(2-ethylexyl)phthalate (DEHP)). The discussions for each case study at the MSC based on the lines of evidence will be presented explaining the resoning for the change in the proposed testing strategy for the BP subsance evaluation case and for the identification of DEHP as an SVHC with endocrine disruptive properties towards wildlife.

360

Identification of environmental endocrine disrupting chemicals under REACH - Experience and challenges

S. Frauke, Federal Environmental Agency, Germany; J. Arning, German Environment Agency (Umweltbundesamt) / Chemicals

Horizontally harmonized criteria for the identification of endocrine disrupting chemicals (ED) are still missing at the EU level. While such criteria are urgently needed to regulate ED substances under the plant protection product and biocidal product regulation (PPPR and BPR), under REACH the identification and regulation of ED is already possible without the lack of harmonized criteria. This is due to the fact that under REACH the identification of an ED can be treated separately from the following risk management, which is not the case for plant protection products and biocides. The work presented here will reflect our experience with the identification of ED in the environment under REACH and tries to work out why from an environmental point of view the identification of ED differs from the approach used for human health risk assessment. The resulting problems concerning the design of harmonized identification criteria are also addressed. The differences and the commonalities of the PPPR and BPR regarding the identification and its consequences are summarised. The process under REACH is discussed in detail and using examples from already identified ED it is presented how the requirements of Art. 57 (f) of the REACH regulation can be fulfilled without having horizontal criteria for ED identification. It is generally agreed that there are many uncertainties in carrying out a risk assessment of ED. Many are not specific to EDs but some factors may be particularly relevant to some ED. Endocrine Disruptors may cause adverse effects in a variety of species including very different taxa. With respect to this we have the following position: It is at the moment impossible to identify, which species are sufficiently representatives for wildlife with regard to endocrine effects. The available test methods are very limited and especially with regard to invertebrates do not cover sensitive taxa and life stages. It might be possible to overcome these shortcomings in future but based on the already available indications of harmful effects in the environment, it seems not to be adequate to await this progress. Thus, we think that the ED identification should be based on WHO/IPCS definition and should consider that uncertainties are high for ED with regard to environment. This should result in a hazard based regulation but regulatory consequences for different legislation need to be taken into account (i.e. exemptions needed for plant protection products and biocides).

361

What, oh what, is the mode of action? Use of the acute to chronic ratio in a weight of evidence for endocrine activity

E.M. Mihaich, ER2; K.K. Coady, The Dow Chemical Company / Toxicology Environmental Research and Consulting; J. Woelz, Currenta; R. Werner, Covestro Germany AG; P. Stoldt, Envigo CRS Switzerland Ltd

Extensive discussion is occurring in the European Union and internationally on how to identify and potentially categorize endocrine disruptors (ED). There is general agreement that the evaluation of ED should be based on the WHO/IPCS (2002) definition. According to WHO/IPCS: *"An endocrine disruptor is an exogenous substance or mixture that alters function(s) of the endocrine system and consequently causes adverse effects in an intact organism, or its progeny, or (sub)populations*." This definition embodies the key elements of adversity, endocrine mode of action (MoA), and a causal link between endocrine activity and adverse effect. The mere existence of an endocrine mode of action (*i.e*., endocrine activity) is not a harmful property, a type of toxic effect, or a hazard. Rather, endocrine activity, if causally linked to an adverse outcome, can potentially lead to a hazard to health or to the environment, particularly after long-term exposure. Defining that there is a causal link between an indication of activity and an adverse effect, particularly one that would be the lead or primary toxic effect most relevant for risk assessment is important. Identifying the causal link can be difficult in studies with many apical endpoints. The acute to chronic ratio (ACR) can be informative in situations where there are in vitro indications of activity but the weight of evidence for an in vivo causal link to an adverse outcome is not clear. The extensive database for BPA will be used to illustrate a robust weight of evidence process for a substance with weak in vitro estrogenic activity and in vivo biomarker responses. Although a weak estrogenic activity is apparent for BPA among various fish species, the profile of adverse effects that have been measured in BPA-exposed aquatic vertebrates and are used in ecological risk assessments (*i.e*., effects on survival, growth, development, and reproduction) are not all definitively linked to a weak estrogenic mode of action. The ACR for BPA, in comparison with substances with hormonal modes of action, will be used to help clarify the differences between substances that do have chronic hormonal toxicities and those that might be responding to general, systemic toxicity. The orders of magnitude difference in the ACR for BPA, compared to substances such as estradiol and ethynl estradiol, suggest that BPA's lead mode of action is related to non-specific, systemic toxicity rather than an endocrine specific response.

362

Opportunities and challenges in using rodent data to evaluate ecological hazard of potential endocrine active substances

C. Prosser, M. Lampi, ExxonMobil Biomedical Sciences, Inc.; M. Leon Paumen, ExxonMobil Biomedical Sciences / ExxonMobil Biomedical Sciences TES Division

Inter-species extrapolation of toxicity data is a substantial challenge for environmental risk assessment. Due to practical limitation in the number of *in vivo* assays that can be conducted, and the desire to reduce animal testing, regulatory decisions commonly rely on few whole-animal studies. Additionally, ecotoxicological hazard assessments most often rely solely on aquatic species (fish and amphibians). This has led some to consider the use of rodent data to evaluate endocrine active compounds for terrestrial assessment. While this has advantages, including a direct comparison to terrestrial mammalian species, evaluating such data in the context of endocrine disruption encompasses many challenges and unknowns. For example, macroscopic (e.g. routes of exposure and life histories) and microscopic (cellular receptors and pharmacokinetics) differences between rodents and other terrestrial vertebrates (including avian and reptilian species) are poorly understood. Additionally, field-derived metabolic rates have shown to vary widely between vertebrate taxonomic groups (up to five orders of magnitude). Energetics will influence behavior, biochemical pathways and food intake, all of which may alter hazard potential. Furthermore, rodents in a laboratory will not be subject to the same seasonal influences, which greatly affect the endocrine system, and therefore may not exhibit similar exposure effects/sensitivities. Finally, while rodent models and human health are focused on hazards to individuals, investigating endocrine disruption in the environment requires evaluating adverse effects at the population level. Here we further discuss some challenges and opportunities in extrapolating rodent data to adverse environmental effects at the population level. This discussion will inform future research and regulatory action when assessing ecological hazard assessment. While rodent data may be reasonable to evaluate endocrine disruption for terrestrial species, it is not universal, and factors such as exposure route, pharmacokinetics, and taxonomic differences in metabolic pathways must be considered when determining adverse population level effects in the environment.

Quality Standards for Nonylphenol and Octylphenol in sediment based on ecotoxicological studies
S. Valsecchi, Water Research Institute - Italian National Research Council IRSA-CNR; H. Clausen, Danish Environmental Protection Agency; M. Mazzoni, M. Rusconi, Water Research Institute - Italian National Research Council IRSA-CNR / Water Research Institute; R. Bettinetti, University of Insubria; S. Polesello, Water Research Institute - Italian National Research Council IRSA-CNR / Water Research Institute
Nonylphenol (NP) and octylphenol (OP) are degradation products of alkylphenolethoxylates (APE), non-ionic surfactants employed for more than 40 years, which elicit endocrine disrupting effects on aquatic organisms. For this reason, since 2001, they have been included in the list of priority hazardous substances of the Water Framework Directive. Quality standards (QS) for different environmental compartments were set out, and NP, OP and APE have been subject to EU restrictive regulation on marketing and use since 2003. The significant decrease in NP and OP concentrations in water in the last years demonstrates the effectiveness of the control measures that the European Union put in place to control these priority hazardous substances. However NP and OP concentrations in monitored sediments are often above QS for sediments raising doubts about the reliability of these QSs. In the framework of a European initiative for the harmonization and derivation of Environmental Quality Standards, Italy and Denmark collaborated to derive a robust and reliable QSsed for these two priority substances. Toxicological tests with *Chironomus riparius, Lumbriculus variegatus and Hyalella Azteca* were carried out according to OECD and USEPA guidelines for both NP and OP. The test results and literature data were combined and a QSsed for NP and for OP based on ecotoxicological studies was derived according to the Technical Guidance Document on deriving EQS (CIS-WFD Guidance n. 27). The estimated QSs for sediment, normalised to organic carbon content, were 37 and 25 mg/kg OC respectively for OP and for NP. These QSs for sediment, based on ecotoxicological studies, are about 100 higher the previously derived QSs which were calculated by Equilibrium Partition (EqP) approach.

Advancements in life cycle impact assessment method development (I)

364
A first step towards the consideration of habitat fragmentation in LCA
P. Larrey-Lassalle, IRSTEA Montpellier / UMR ITAP ELSA; E. Loiseau, National Research Institute of Science and Technology for Environment and Agriculture - Irstea; E. Blanco-Perez, National Research Institute of Science and Technology for Environment and Agriculture - Irstea / UMR ITAP ELSA; S. Alleaume, National Research Institute of Science and Technology for Environment and Agriculture - Irstea / UMR TETIS; P. Roux, National Research Institute of Science and Technology for Environment and Agriculture Irstea / UMR ITAP ELSA; M. Lopez-Ferber, Ecole des Mines dAlès; R.K. Rosenbaum, National Research Institute of Science and Technology for Environment and Agriculture - Irstea / UMR ITAP
Fragmentation is commonly defined as a process in which "a large expanse of habitat is transformed into a number of smaller patches of smaller total area, isolated from each other by a matrix of habitats unlike the original". Alongside climate change or pollution, habitat change and fragmentation was identified by the Millennium Ecosystem Assessment as one of the five direct drivers of biodiversity loss. Given this fact, it seems to be of paramount importance to include this driver in LCA methods. To this end, the last theoretical frameworks of land-use impact chains proposed to include fragmentation as a human intervention leading to biodiversity loss. Nonetheless, the UNEP-SETAC land-use group recently pointed out that habitat composition and configuration, including fragmentation, seemed to be under-represented in impact assessment models and should be considered, particularly when dealing with Species Area Relationships (SAR). A literature review on the ecology field was performed in order to define fragmentation and its relating environmental mechanism and to identify quantitative approaches that attempt to consider the impacts of fragmentation on biodiversity loss. Among these approaches, recent work on adapting the SAR in order to include fragmentation effects along with area loss seems to be promising. The Species Fragmented-Area Relationship (SFAR) uses the metapopulation capacity λ to describe the degree of fragmentation of a landscape. This work proposes to adopt this method to consider fragmentation in LCA. First, we developed a routine procedure to derive quantitative values of λ for different landscapes. Second, we applied the methodology to two contrasted Amazonian landscapes to test its feasibility and interest. The results show that fragmentation has important effects on spatial configuration and should be included in LCIA methods. However, one limitation of the SFAR is its relatively recent methodological development, and the fact that so far, it has only been tested in an Amazonian ecoregion for birds, while a larger spatial and taxa coverage for a practical use in LCA is required. Therefore, it is important to assess the validity of the method in other contexts. In conclusion, this exploratory work aimed at assessing the feasibility of including one of the most comprehensive and operational ecological models for fragmentation into LCA. The next step will be to derive CFs for land-use from the SFAR in order to conclude on its relevance.

365
Advancing marine impact assessment within life cycle assessment (LCA)
F. Verones, NTNU / Department of Energy and Process Engineering; J.S. Woods, NTNU / Industrial Ecology Programme; K. Veltman, University of Michigan / Department of Environmental Health Sciences; M. Huijbregts, Radboud University Nijmegen / Department of Environmental Science; E.G. Hertwich, Yale University
Assessment of ecosystem damage in life cycle assessment (LCA) has greatly progressed over recent years. However, marine ecosystems remain heavily underrepresented, despite their importance for anthropogenic activities, both as a source of resources and receptor of waste, meaning that impacts on marine ecosystems are often assumed negligible. We identified seven major drivers for marine biodiversity loss: climate change, seabed damage, ocean acidification, marine eutrophication, overexploitation, invasive species and plastic waste. Characterization factors associated to some of these impact categories have already been developed. However, (spatial) detail and (geographical and taxonomic) coverage remain limited. For other impact categories, such as marine plastic debris, no LCA approaches exist yet. Furthermore, others have only case–study-based LCA approaches, for example invasive species. For all of the seven drivers, models predicting the distribution, intensity and damage of anthropogenic interventions, both temporally and spatially, are available. We therefore review possible quantitative approaches for including, or refining the representation of, these seven impact categories in LCA. We find that it is possible to derive impact indicators for all considered drivers. However, the levels of detail, coverage and uncertainty of the factors may still vary. In addition, fate and exposure factors are more readily developable than effect factors. For plastic debris, for example, models are available that describe the transport of plastic waste from the land to the ocean and the subsequent accumulation procedure within the ocean itself. These approaches can be translated into a fate factor by assigning to each country the fraction of plastic that is ending up in one of the different accumulation zones in the ocean. Models to estimate the effects on biodiversity are less developed and variation in model sophistication is large. Whilst well-established species sensitivity distributions can, for example, be used for marine eutrophication, ocean acidification and particle sedimentation, models for indicating the effect of plastic debris on marine biodiversity are completely lacking. We recommend adapting available quantitative approaches to generate new and refine existing fate models, and to further development of effect factors based on species richness loss, analogous to potentially disappeared fractions of species.

366
Accounting for biodiversity impacts of seabed damage in life cycle assessment
J.S. Woods; F. Verones, NTNU / Department of Energy and Process Engineering
Traditionally life cycle assessment (LCA) has mostly focused on estimating impacts on terrestrial and freshwater ecosystems. Due to limited coverage of marine-focused operational life cycle impact assessment (LCIA) methodologies, impacts on marine ecosystems are often assumed negligible. Given the importance of the marine environment for human society, for example through provision of mineral and fish resources, and a desire for LCA to be a comprehensive environmental assessment tool, development of novel marine-focused LCIA methodologies is essential. Even though it is a predominant driver of biodiversity loss in marine ecosystems, one of the neglected categories is seabed damage. Some first steps in methodological development for this impact category have been undertaken in the LCA community. However, limitations remained, particularly because of limited consideration for biodiversity-specific impacts. We established a generalised impact pathway triggered by seabed damaging activities. This impact pathway applies for three main modes of impact: 1) abrasion (e.g. benthic trawl fisheries), 2) smothering (e.g. deposition of dredged material, cutting pile formation due to offshore oil and gas production) and 3) extraction (e.g. aggregate dredging). We developed characterisation factors (CFs) using a modelling approach analagous to that developed for the assessment of land use impacts. As such, the overall impact of seabed damage is a function of disturbance characteristics (scale and intensity), initial response of the benthic community, duration of the anthropogenic activity and subsequent physical and ecological recovery of the seabed. Our CFs allow for quantification of temporary impacts in terms of potentially disappeared fraction of species (PDF) due to occupation ($PDF.m^{-2}.yr^{-1}$) and transformation ($PDF.m^{-2}$) of the seabed. Our CFs also allow for quantification of permanent impacts ($PDF.m^{-2}$) if complete recovery is not

expected. The CFs are mode of impact specific and spatially differentiated according to the large marine ecosystem (LME) biogeographical system and seabed substrate. Given that most anthropogenic seabed damage occurs within continental shelf areas, our developed methodology is applicable for the global extent of the 66 LME units, which covers all continental shelf areas globally. For the first time we are able to account for biodiversity impacts of seabed damaging activities within LCA on a global scale (LME) and at endpoint level.

367
Habitat suitability: water use impact assessment for ecosystems beyond counting species
M. Damiani, IRSTEA Montpellier / UMR ITAP ELSA; E. Loiseau, M. Núñez, National Research Institute of Science and Technology for Environment and Agriculture Irstea; P. Roux, National Research Institute of Science and Technology for Environment and Agriculture Irstea / UMR ITAP ELSA; R.K. Rosenbaum, National Research Institute of Science and Technology for Environment and Agriculture - Irstea / UMR ITAP
Assessment of water-use impacts on ecosystem quality in LCA is a relatively recent research domain and still undergoing continuous development. The most recent approaches develop characterization factors by differentiating *fate*, *exposure,* and *effect factors* for distinct water sources and ecosystems. Even though, there is no consensus about what are the midpoint and endpoint indicators to be chosen to better represent impacts on the *Ecosystem Quality* area of protection. Current methods are based on describing ecosystem quality by means of biodiversity loss indicators. If choosing such type of endpoint unit allows a straightforward representation of results, they still carry a lot of uncertainty due to difficulties in isolating direct causal relationships between fate and effect factors, and between midpoint and endpoint indicators. Moreover, most of the methods face problems of data availability, along with a limited spatial coverage. This raises the question whether species loss is suitable and representative for describing freshwater ecosystem quality in LCA. Adopting species-loss-based indicators for water-use impacts on ecosystems, conceptually conflicts with the natural behaviour of aquatic ecosystems, where species disappearance usually occurs in case of extreme or long term habitat alteration instead of marginal changes. Therefore, the dynamics of stressors should be characterized in order to assess impacts of water use. Eco-hydrological methods identify variations of ecologically significant parameters of flow regimes related to ecological responses in freshwater habitats. Microhabitat simulation methods are used to build habitat suitability curves for single or grouped fish species based on these variations. This study is aimed at developing an effect factor based on eco-hydrological approaches. We present first results showing the application in a selected case study in France. Going beyond indicators of species richness allows to isolate the cause-effect chain between water deprivation and ecological response from other stressors. The potential change in habitat suitability could be used as a proxy to indicate the response to habitat change for target species. Building an impact assessment method on significant relationships between freshwater ecosystems and environmental flows may ultimately require a translation into biodiversity metrics to allow a straightforward comparison and aggregation of results with other impact categories and pathways.

368
Natural Resources as an Area of Protection in LCA - outcomes of the discussion by the working group on resources within the UNEP-SETAC Life Cycle Initiative
T. Sonderegger, Institute of Environmental Engineering; J. Dewulf, EC JRC - IES / Sustainability Assessment unit; P. Fantke, Technical University of Denmark / Quantitative Sustainability Assessment Division; S. Pfister, F. Stoessel, ETH Zurich / Institute of Environmental Engineering; F. Verones, NTNU / Department of Energy and Process Engineering; M. Vieira; B.P. Weidema, Aalborg University / Danish Centre for Environmental Assessment; S. Hellweg, ETH Zurich / Institute of Environmental Engineering
The topic of resources as an area of protection (AoP) in life cycle assessment (LCA) is being discussed within an expert group under the umbrella of the Life Cycle Initiative by the United Nations Environment Programme (UNEP) and the Society for Environmental Toxicology and Chemistry (SETAC). The AoP 'Natural Resources' is neither well defined nor agreed upon. Furthermore, there is currently no life cycle impact assessment (LCIA) method available that is able to consistently assess impacts at midpoint and endpoint level across different resource categories (minerals/metals and fossil fuels, water, land/soil, biotic resources like wild plants and animals). Definitions and categorizations of natural resources differ and there is no agreement on what methods should be considered midpoint or endpoint methods because there is no agreement (at midpoint and endpoint) on what impact should be assessed (is it reduced availability, is it depletion, is it increased energy use or costs due to future resource extraction, etc.?). The merit of this working group is the broad analysis of available methods considering different resources and their integrated discussion according to the methods' underlying principles (e.g. use-to-availability ratios, backup technology approaches, etc.). This is the basis on which recommendations for best practice with existing methods and indications for further research and development will be given. At the time of the SETAC 2016 conference, the group should have these recommendations ready.

369
Interpretation of LCA results: significant issues also informed by the environmental footprints pilots
V. Castellani, European. Commission - Joint Research Centre / Institute for Environment and Sustainability; L. Benini, European Commission DG Joint Research Centre / Institute for Environment and Sustainability Sustainability Assessment Unit; L. Zampori, European Commision DG Joint Research Centre / Institute of Environment and Sustainability; S. Corrado, Universita Cattolica / Institute of Agricultural and Environmental Chemistry; S. Sala, European Commission - Joint Research Centre / Sustainability Assessment unit; R. Pant, European Commission / Institute for Environment and Sustainability
According to ISO 14040 interpretation is the phase of LCA in which the findings from the inventory analysis and the impact assessment are considered together; it should deliver results that are consistent with the defined goal and scope and which reach conclusions, explain limitations and provide recommendations. ISO 14044 further specifies that interpretation comprises the following elements: i) identification of the significant issues based on the results of the LCI and LCIA phases of LCA; ii) an evaluation that considers completeness, sensitivity and consistency checks; iii) conclusions, limitations, and recommendations. The Product Environmental Footprint (PEF) Guide [1] explains that interpretation of the results of a PEF study serves two purposes: i) to ensure that the performance of the PEF model corresponds to the goals and quality requirements of the study; in this sense, PEF interpretation may inform iterative improvements of the PEF model until all goals and requirements are met; and ii) to derive robust conclusions and recommendations from the analysis, for example in support of environmental improvements. Within the work done in support to PEF/OEF, the JRC has perfomed some studies and some tests in order to identify the most relevant issues to be considered in the interpretation phase. The final aim of this work is to gain insights on cross-cutting issues affecting all the phases of a life cycle study and to provide guidance and support to practitioners and researchers in the intepretation phase. The presentation will show and discuss the results of some preliminary tests done within this framework including 1. the influence to final results of the selection and the modeling assumptions in secondary inventory dataset; 2. sensitivity analysis of impact assessment modeling; 3. sensitivity analysis of normalisation, including uncertaitnty analysis; and 4. sensitivity analysis of weighting.

Passive sampling of organic micropollutants and toxicity assessment: opportunities, challenges and innovations (I)

370
Detecting POPs profiles across the Atlantic Ocean using polyethlyene samplers
C. Sun, University of Rhode Island; R. Lohmann, University of Rhode Island / Graduate School of Oceanography; T. Soltwedel, Alfred-Wegener-Institut Helmholtz-Zentrum für Polar- und Meeresforschung; E. Bauerfeind, Alfred Wegener Institute
Little is known of the distribution of persistent organic pollutants (POPs) in the deep ocean. Polyethylene passive samplers were used to detect the vertical distribution of truly dissolved POPs at two sites in the Atlantic Ocean. Samplers were deployed at five depths covering 26-2535 m in the northern Atlantic and Tropical Atlantic, in approximately one year deployments. Samplers of different thickness were used to determine the state of equilibrium POPs reached in the passive samplers. Comparable sampling rates were obtained from model derived results (5 & 4 L/day) and performance reference compounds derived results (8.7 & 4.9 L/day). Concentrations of POPs detected in the North Atlantic near the surface (e.g. $\sum_{14}$PCB: 0.84 pg L^{-1}) were similar to previous measurements. Currents seemed more important in moving POPs to deeper water masses than the biological pump. The ratio of PCB concentrations in near surface waters (excluding PCB-28) between the two sites was inversely correlated with congeners' sub-cooled liquid vapour pressure, in support of the latitudinal fractionation. The results presented here implied a significant amount of HCB is stored in the Atlantic Ocean (4.8-26 % of the global HCB environmental burdens), contrasting traditional beliefs that POPs do not reach the deep ocean.

371
Vertical distribution of organic contaminants in harbour waters assessed by passive sampling
y. aminot; A. Belles, C. Alary, Department of Civil and Environmental Engineering, Mines Douai, LGCGE-GCE; J.W. Readman, Biogeochemistry Research Centre, Plymouth University
Coastal and estuarine areas receive contaminants from wastewater discharges and littoral activities such as boating, sea trade and fisheries as well as from upstream inputs through riverine discharges and soil washout. Assessing the distribution of these contaminants in water bodies provides insights for the understanding of their sources and fate, hence allowing a better management of our waters. In particular, a vertical profile of pollutants can indicate sources originating from the water

surface, freshwater-derived material if correlated to salinity or surface processes such as photodegradation or evaporation at the air-sea interface. For this purpose, passive sampling is a method of choice for the monitoring of moderately hydrophobic organic contaminants at marine trace levels as they are able to concentrate the analytes in-situ, thus providing limits of detection that can be as low as the $pg.L^{-1}$. In this study, vertical distributions of selected organic contaminants were assessed in an English marina from the surface to more than 3 m depth. Polyethylene strips were held vertically and immersed for 18 days from floating pontoons. Following deployment, the strips were sliced to provide 46 depth related sub-samples. A section of approximatively 1 cm at the surface allowed profiling of the sea-surface microlayer. Time-weighted average concentrations were calculated for Polycyclic Aromatic Hydrocarbons (PAH) by using passive sampling and the performance and reference compound approach. As an example, results revealed a surface enrichment for phenanthrene and chrysene with a 5-fold increase in the first 50 cm, whilst fluoranthene and pyrene exhibited decreasing concentrations closer to the surface. Source tracking of the PAHs indicated an oil-derived contamination at the surface with enhanced combustion derived PAH concentrations at lower depths. Measurements were further extended to selected antifouling compounds, organophosphorous flame retardants and personal care products. The vertical profiles of detected compounds exhibited comparable distributions to the model PAH's which aided in interpretation of their relative sources and fates. This study demonstrates that passive sampling can provide a cost-effective and novel monitoring tool to investigate the sources and fate of contaminants whilst providing important information on compound dependent vertical profiling in contaminated waters.

372

Two activities on passive sampling in water and sediment in the North Atlantic within the OSPAR/ICES community

F. Smedes, Masaryk University / RECETOX Research centre for toxic compounds in the environment; T. van der Zande, Wetsus / Laboratory; H. Beeltje, TNO / Applied environmental chemistry; P. Kukucka, Masaryk University / RECETOX Research Centre for Toxic Compounds in the Environment; D. Vethaak, DELTARES / Marine and Coastal systems; I. Davies, Marine Scotland Science, Marine Laboratory

OSPAR Convention is the current framework for international cooperation on environmental protection in the North-East Atlantic and has installed a programme for baseline monitoring of environmental status, covering both the spatial distribution of contaminants and temporal trends. Generally, OSPAR countries monitor chemical contaminants in sediment and/or biota. Both matrices suffer from compositional heterogeneity throughout the OSPAR. To reduce sample varibility OSPAR is considering the inclusion of passive sampling in its monitoring programmes, and a number of preparatory actions on passives sampling have been conducted within the OSPAR/ICES scientific community, including the sampling of water as well as sediment. In 2006, the **OSPAR/ICES Passive Sampling Trial Survey** (PSTS) was organised with 13 laboratories participating and samples from 30 stations distributed across the ICES area applying polymer sheet samplers and bottles with 10 μm silicon polymer coatings for sediment equilibrations. Participants exposed sheet samplers were exposed to water at each of the selected stations equilibrated sedments in the laboratory. Aanalysis of duplicate samplers (sheets and bottles)by the participants and the central laboratory gave infomation on the between laboaratory variability The data produced by the central laboratory for all station allowedto evaluate the data in spatial perspective as well as over matrices. In another projekct (ICON/2008) sediment was collected at 13 stations between Iceland and the Mediterranean and equilibrated sheet samplers for 6 months . Sheet were anaysed for PRCs, PCBs, PAHs, PBDEs, OCPs, alkylphospahates, and dioxins and dibenzofurans. Passive sampling proved to be extremely sensitive and was able to detect many compounds that were not detected by whole sediment analysis. The presentation will demonstrate the power of passive sampling to reveal spatial distributions over large areas.

Advancing in situ passive sampling techniques to quantify chemical activity gradients across the sediment-water and benthic boundary interfaces in large water bodies

D. Gilbert, NGI / Department of Environmental Sciences; N. Berrojalbiz, E. Eek, Norwegian Geotechnical Institute; A.M. Oen, Norwegian Geotechnical Inst. / Dept Environmental Engineering; H. Arp, NGI / Environmental Engineering

Passive sampling is increasingly recognized as a superior monitoring tool for nonpolar organic chemicals in water and sediment. Beyond monitoring, passive sampling offers opportunities to explore contaminant transport mechanisms in large water bodies; and the potential of these oppourtinities have yet to be fully exploited. Recently developed sediment porewater profilers were equipped with both μm-thin low-density polyethylene (LDPE) films and silicone (PDMS) membranes as passive samplers for polycyclic aromatic hydrocarbons (PAHs) and polychlorinated biphenyls (PCBs), offering a 2.5 cm vertical resolution of contaminant concentrations within and across the sediment-water interface and the benthic boundary layer. Passive samplers of various thicknesses were used in order to assess whether chemical equilibrium was reached during the 2 and 5 months exposure time. Passive samplers were also exposed in the water column above the sediment porewater profilers. Parallel deployment of different passive sampling materials proved to be a simple and effective tool to validate obtained passvie sampling data. Passive sampling across the sediment-water interface using the newly developed sediment porewater profiler in combination with passive sampler deployment in the water column facilitated a vertical mapping of HOC contamination and allowed a thermodynamically based assessment of contaminant fluxes.

374

Determining the release of hydrophobic organic contaminants from sediment by in-situ benthic flow-through flux chambers

L. Mustajärvi, Stockholm University / Department of Environmental Science and Analytical Chemistry ACES; E. Eek, G. Cornelissen, Norwegian Geotechnical Institute; A. Eriksson-Wiklund, Stockholm University / Environmental Science and Analytical Chemistry ACES; A. Sobek, Stockholm University / Department of Environmental Science and Analytical Chemistry ACES

Contaminated sediment may act as a source of hydrophobic organic contaminats (HOCs) to water, such as in the Baltic Sea where high chemical activity ratios between pore water and bottom water for dioxins were observed, demonstrating a potential release of dioxins from sediment to the water column. Quantification of the sediment-water flux of HOCs is important to enable assessment of the risk associated with contaminated sediment. Currently used methods to estimate the flux of HOCs from sediment to water are either indirect or direct by the use of *in-situ* flux chambers. Existing *in-situ* flux chambers are closed with no water flow through the chamber. Oxygen is therefore consumed during the deployment and benthic organisms are severely disturbed. This is a drawback of closed chambers since bioturbation may have a significant impact on the sediment-water flux. This study presents a novel *in-situ* benthic flow-through flux chamber for determination of the release of HOCs from sediment to water. The water in the chamber is kept at ambient oxygen concentration by pumping of bottom water through the chamber. The measured flux thereby includes effects due to bioturbation. Water is pumped through the chamber to oxygenate the water inside the chamber, and passes first a sorbent at the inlet to strip it of any contaminants. At the chamber outlet, a second sorbent captures contaminants that were released from the sediment during deployment. Three benthic flow-through flux chambers were deployed for 3 days in a contaminated Baltic Sea Bay (south of Stockholm) for *in-situ* testing. The flux of PAHs and PCBs [$ng\ m^{-2}d^{-1}$] was determined from the mass of compound quantified in the outlet sorbent, the area of the benthic chamber and the deployment period. 15 PAHs and 7 PCBs were analysed. Closed flux chambers were deployed in parallell and passive samplers were used to collect the freely dissolved fraction of PCBs and PAHs in bottom water and porewater (work in progress). The flux individual PAHs and PCB congeners from sediment to bottom water ranged between 60-2300 [$ng\ m^{-2}d^{-1}$] and 6-170 [$ng\ m^{-2}d^{-1}$], respectively. The low variance among the 3 replicate flux measurements supports the robustness of the *in-situ* flux measurements using the novel chamber design. The results will be further compared to flux estimates calculated from chemical activity ratios (pore water and bottom water) and with flux measurements from closed chambers deployed in parallell.

375

Application of POCIS and new mixed polymer passive sampler for monitoring organic contaminants in the river Saar and the outflow of a wastewater treatment plant

Y. Jeong, KIST Europe; A. Schaeffer, K. Smith, RWTH Aachen University / Institute for Environmental Research

A broad spectrum of organic contaminants is released into aquatic environments and affects the water quality. For monitoring of these aquatic contaminants, passive sampling is a promising tool with a number of advantages over grab sampling. The objectives of this study were (1) to determine the dissolved concentrations of organic contaminant in the river Saar and effluent of a wastewater treatment plant (WWTP) which discharges into the river and (2) to compare the performance of two types of passive samplers. Two passive sampler types were deployed over five weeks (May-June 2015) at three locations along the river Saar, at the confluence of the rivers Saar and Mosel and in a WWTP effluent discharging into the river. One sampler was the Polar Organic Chemical Integrative Sampler (POCIS), where Oasis HLB was sandwiched between two polyethersulfone (PES) membranes. The second sampler was a mixed polymer sampler (MPS) made of Oasis HLB embedded in polydimethylsiloxane (PDMS) disks and enclosed in copper mesh to limit biofouling. PDMS is widely used for sampling neutral hydrophobic organic compounds in water due to its reversible sorption and high internal permeability. Compared to PDMS alone, the MPS has an increased affinity towards a wide range of polar contaminants with the added advantage that it makes handling of the powdery Oasis HLB easier. After five weeks deployment, targeted 46 organic contaminants of diverse log K_{OW} -0.03 for atenolol to 6.25 for miconazole were analyzed directly via LC-MS/MS. The measured sampler concentrations were calculated back to time-weighted average water concentration using sampling rates for each compound which were determined in the separate experiment. Both sampler types performed well and could detect a range of organic contaminants. Low concentrations (ng to sub μg per litre) of 27 compounds were detected in both the POCIS and MPS extracts. This includes 6 compounds from the WFD priority list, which were detected all sampling sites. For the POCIS, some of the compounds accumulated significantly in the PES membranes, which complicates interpretation of the results. The polymer block nature of the MPS made this particularly robust to handle during deployment and extraction. Future efforts are concentrated on applying the mixed polymer as a passive dosing phase, with a view to directly integrating passive sampling and dosing for measuring environmental mixture toxicity for polar and non-polar organic compounds.

Pushing nanoparticle studies to the limit - working at environmentally relevant concentrations and with complex matrices (II)

376

Release of TiO2-(NP) from construction landfills

R. Kaegi; B. Sinnet, Eawag Swiss Federal Institute of Aquatic Science and Technology; A. Englert, M. Burkhardt, UMTEC, HSR Hochschule für Technik Rappserswil

After their use, a large fraction of nanomaterials (NMs) will be deposited in landfills, which are considered as terminal sinks for the NMs. However, experimental data and field measurements supporting this assumption are mostly lacking. Production volumes of NMs are still limited, but TiO_2 particles are used in large quantities mainly as white pigments since many years. We, thus, used TiO_2 particles as a proxy for other NMs, which may become relevant in the future, and investigated the release of TiO_2 particles from a landfill dominated by construction materials. The pH and the temperature of the oxygen saturated runoff were ~ 7 mg/l and 12 °C. Average discharge rates were a few m^3/d but increased to more than 100 m^3/d after heavy rain events. The total suspended solids (TSS) were mostly between 2 – 20 mg/l. One liter of runoff was filtered through 0.2 μm polyacetate filters and acid digested using a microwave assisted acid digestion system. The digest was diluted 1:50 with DDI water and Ti was measured on an ICP-OES. The Ti concentrations were ~10 μg/l, expect after one heavy rain event, when more than 150 μg/L Ti was measured in the runoff. This exceptionally high Ti concentration was paralleled with TSS content of more than 70 mg/l. For electron microscopy analysis, runoff was either filtered (0.4 μm) or the supernatant of centrifuged samples (5 min, 700 g) was directly centrifuged on TEM grids. About 1% of all particles (> 10'000) detected using automated electron microscopy was identified as TiO_2 particles. The particle number of all particles and also of the TiO_2 particles showed an exponential increase with decreasing particle diameter down to 0.5 μm, corresponding to the detection limit resulting from the applied microscope settings. More detailed analysis of individual particles from the supernatant in the electron microscope revealed individual TiO_2 particles in the nano-range. Single particle ICP-MS analysis revealed a total number concentration of TiO_2 particles (< 500 nm) in the order of 10^5 # / ml. These results indicate that individual TiO_2 particles are released from landfills. Although the amount of TiO_2 particles released from landfills is currently orders of magnitudes smaller than the natural background of TiO_2 in surface waters, the predicted increase in the use of NMs in building materials, consumer products, electronic devices etc. calls for a more detailed analysis of the release mechanisms of NMs from landfill sites.

Varieties of nano-textile exposure: comprehensive sequential aging of fabrics to sunlight, washing and landfilling

D.M. Mitrano, EMPA Technology & Society Lab / Environmental Risk and Management; E. Lombi, University of South Australia / Future Industries Institute; Y. Arroyo Rojas Dasilva, Empa Swiss Federal Laboratories for Materials Science and Technology; S. Motellier, CEA Liten; B. Nowack, EMPA

The potential for nanomaterials to be released from consumer goods is not in itself a new topic, but the basis of scientific understanding of released particles and the transformations they may undergo during the products life cycle (e.g. during storage, use and disposal) is often hampered by the narrow scope of many research endeavors in terms of both the breadth of variables studied and the completeness of characterization using multiple analytical methods. Additionally, studies of sequential aging of products representing multiple stages of the life cycle are scarce. In order to bridge these gaps for the release of nanomaterials from textiles, we conducted a comprehensive suite of studies which allowed us to suggest some overarching themes for finding important mechanisms and parameters for particle transformations when still adhered to the fabric or when released. Laboratory prepared nano-enhanced fabrics were subjected to sequential combinations of sunlight irradiation, washing (in seven different detergent formulas). Characterization is divided into two groups: analysis of solutions (washing and landfill leachate) and analysis of the NP fraction that remained on the fabric. Analytical techniques included single particle spICP-MS and TEM of the released particles, fabric digestion and total metal analysis after each exposure scenario, and both SEM and XANES analysis of the textiles for the visual integrity and speciation of Ag, respectively. Some broad generalizations suggest that sunlight irradiation hinders further speciation upon washing (as suggested by XANES). More Ag is released from fabrics than Au suggesting additional chemical influences and while a size effect may also be in play, the capping agent plays the largest role. However, when release does occur, a large proportion of particles are released into the wash water with little to no alteration of the size compared to the primary particle size (as determined by sp-ICP-MS). As seen in our previous work, detergent chemistry plays a significant role in concentrations of Ag released, where those containing oxidizing agents clearly assist in release of Ag particles (but not Au NPs, again inferring the additional chemical reactions specific to Ag). This undertaking of a large matrix of variables makes us more confident to make more overarching characterizations since trends can be monitored across more variables than in any other nano-composite release study to date.

Fate and Bioaccumulation of Nanosilver in a Lake Ecosystem

D. Rearick, Trent University / Biology; J. Martin, Trent University / Water Quality Centre; K. Cetinic, A. Conine, P. Frost, Trent University / Biology; H. Hintelmann, Trent University / Water Quality Centre; A. Scott, Trent University / Biology; L. Telgmann, Trent University / Water Quality Center; M.A. Xenopoulos, Trent University / Biology; C.D. Metcalfe, Trent University / Water Quality Centre

There is potential for the release of AgNP into the aquatic environment through discharges of municipal wastewater. AgNPs undergo dissolution in aerobic environments to release silver ion, which is toxic and has potential for bioaccumulation. The stability and transformations of AgNPs in the aquatic environment are affected by environmental factors, so the fate of AgNPs are expected to vary greatly in natural aquatic ecosystems. We added 15 kg of PVP capped AgNPs over two field seasons to a natural lake ecosystem at the Experimental Lakes Area in Canada. Stock suspensions were prepared from powdered AgNP (PVP capped; 30-80 nm) and these stock suspensions were added to Lake 222 (~600 million litre volume, 6 m maximum depth) at a rate of ~500 g per week, for a total addition of ~9 kg over the first field season (June-October, 2014) and ~6 kg over the second field season (May-August, 2015). Total Ag in the water column of L222 increased over time during both Year 1 and Year 2 of AgNP additions. Concentrations of total Ag immediately adjacent to the site of addition were >200 μg/L, but were in the range of ~5 μg/L in the epilimnion at sites elsewhere in the lake. Analysis by spICP-MS indicated that the size distribution of AgNPs remained similar to the stock suspension added to the lake, although larger particles >200 nm present in the stock were not present in the water column. The concentrations of dissolved Ag were very low (i.e.+to dissolved organic matter. Despite the environmentally relevant (i.e. low ppb) concentrations of Ag in the water and seston, there was bioaccumulation of total Ag in biota sampled throughout the lake. The concentrations of total Ag in the liver tissue of northern pike at the top of the food chain at the end of Year 2 of additions was >2 mg/kg; although the concentrations in other tissues were an order of magnitude lower. The concentrations of total Ag in liver tissues from yellow perch were approximately 25% of the concentrations in pike liver. Overall, these data indicate that AgNPs were relatively stable and widely distributed in the lake. The Ag was readily bioaccumulated in aquatic organisms. There is a possibility that biomagnification is occurring throughout the lake food web, but this requires further investigation to confirm the observation.

Can we find nanoparticles in the Dutch environment?

P. Bauerlein, KWR Watercycle Research Institute / Analytical and Environmental Chemistry; E. Emke, KWR Watercycle Research Institute; A. Carboni, University of Amsterdam IBED Institute / IBED; P. de Voogt, University of Amsterdam / IBED; J. Hofman, University of Bath / Water nnovation and Research Centre; F. Schooneman, Vitens; A. van Wezel, KWR Watercycle Research Institute / Chemical Water Quality and Health

Different types of water in The Netherlands were probed for the presence of several inorganic (Ag, Au, TiO_2) and organic nanoparticles (8 fullerenes) using ICP-MS, Orbitrap-HRMS, field flow fractionation, SEM and EDX. Drinking water abstraction sites varying from dune and bank filtrates, surface waters to ground waters were analysed. Furthermore influent, effluent and sludge of sewage treatment plants, and surface waters near airports and harbours were analysed. Air samples from Rotterdam (city) and Cabauw (village) were analysed for a broad set of metals known to be used as nanomaterials in the automobile industry (Mo, Ti, Fe, Cu, Ag, Ce, W, Pd, Pt, Rh, Zn, Si and B) and also for fullerenes. The data obtained were compared to predicted concentrations in literature. In STPs silver is found in influent (1 - 5 ug/L) and effluent (0.5 - 2 ug/L). In sludge silver was found in concentrations up to 0.3 mg/kg as predicted, SEM and EDX could confirm the presence of silver nanoparticles. Gold is found in both influent (2 - 6 ug/L) and effluent (1.5 - 3 ug/L). SEM also confirmed the presence of gold nanoparticles in the sludge. TiO_2 was detected in all STP influents (25 - 110 ug/L) and effluent (1 - 4 ug/L). All STPs remove about 90% of Ti. C_{60} removal efficiency was between 90 and 99%. Up to 0.2 ng/L of C_{60} was detected in effluent. In influent the concentrations varied between 2 - 19 ng/L. In the remaining water samples, silver was only found in one groundwater sample. Amounts of gold were found in three drinking water winning sites up to 0.25

μg/L. Titanium was found in most surface waters that are used for drinking water production. None of the fullerenes were detected in the other aqueous samples. In air, concentrations of nano-sized metals (PM 0.1) increase with traffic density, however only a few mass percent is present as nanoparticles. C_{60} was found at one location (5 pg/m^3).

380

Innovative combination of spectroscopic techniques to reveal nanoparticle fate in a crop plant

C. Larue, CNRS / Ecolab Laboratoire décologie fonctionnelle et environnement; H. Castillo-Michel, ESRF / ID; R.J. Stein, Ruhr University Bochum / Plant Physiologie Department; B. Fayard, Novitom; E. Pouyet, J. Villanova, ESRF / ID; V. Magnin, ISTerre; N. Trcera, SOLEIL / LUCIA; S. Legros, CEA Grenoble / LITEN; S. Sorieul, CENBG / AIFIRA; G. Sarret, ISTerre / Geochimie

Nanotechnologies are developing fast and in a number of application fields like medicine, sustainable development or plant protection products. These new applications also imply an increased dissemination of nanoparticles (NPs) in the environment. Still, their fate is largely unknown mainly because of the lack of adapted techniques to assess their behavior in complex matrixes (soil, plant or animal). In this study, we report the use of complementary spectroscopic techniques to determine the fate of two different NPs (TiO_2 and Ag) in a crop plant: lettuce (*Lactuca sativa*). The behavior of NPs was elucidated by studying their distribution by micro-X-ray fluorescence (μXRF), their *in situ* speciation by X-ray absorption spectroscopy with a micro-focused beam (μXAS) or in full-field mode and their local quantification by micro-particle induced X-ray emission (μPIXE) and Rutherford backscattering spectroscopy (RBS). After a 7-day exposure, preliminary ICP-MS/ICP-AES data reported a concentration in roots about 6 times higher for Ti than for Ag. μXRF analysis of root cross-sections revealed that the high Ti value was mainly due to the formation of an envelope of Ti around the root. Indeed, metal concentration studied with a laterally resolved technique proved that Ag is more internalized in the roots than Ti and thus potentially more translocated to edible organs. This technique also highlighted the different behavior of those two NPs; Ti was detected mainly as hot spots in the tissue and Ag had a more diffuse and homogeneous signal. This difference was substantiated by XAS analysis. Ag in the root was detected under two oxidation states from 100% Ag^0 to 100% Ag^I and in association with different ligands regardless of plant tissue. The predominant ligand identified by linear combination fitting was a thiol-containing molecule (glutathione), known to be implied in plant detoxification mechanisms. Inversely, Ti was detected unaltered with a TiO_2 anatase crystalline form. New information were also obtained on the effects of NP exposure on the ionome. Both NPs affected the ionome on a similar way, but on the case of Ti only for high concentrations. NPs reduced Cu, Zn and Mn concentrations in the parenchyma and vascular cylinder of the plants. All together and with an appropriate statistical analysis, those techniques permitted to deepen our knowledge about NP fate in plants and to obtain new and original data about their impact on plant ionome.

381

Assessing the Paris city contribution to CeO2 and TiO2 nanoparticles concentrations in the waters of the Seine River by spICPMS and FEG-SEM imaging

K. Phalyvong, Institut de Physique du Globe de Paris; Y. Sivry, IPGP - VAT FR79197534282; H. Pauwels, BRGM; A. Gelabert, L. Cordier, IPGP; G. Wille, X. Bourrat, BRGM; J.F. Ranville, Colorado School of Mines / Chemistry and Geochemistry; M.F. Benedetti, Université Paris Diderot

Engineered nanoparticles (ENPs) are of great interest because of their specific properties which make them useful especially in industrial area. For instance, cerium dioxide NPs (CeO_2NPs) can be found in the automobile domain and titanium dioxide NPs (TiO_2NPs) are used in cosmetics as an UV blocking filter. Nevertheless, these ENPs are expected to be found in the environment at modeled concentration of ppb or ppt levels (1). In order to detect these ENPs at relevant concentrations and among natural NPs, innovative analytical tools are required. A field investigation was done along the Seine River on May, 2015 from upstream to downstream Paris city. single particle Inductively Coupled Plasma-Mass Spectroscopy (spICPMS) (2) and Field Gun Emission - Scanning Electron Microscopy (FEG-SEM) are applied on the river water samples to detect and characterize CeO_2NPs and TiO_2NPs. Moreover, three tributaries (Orge, Marne and Oise rivers) are studied in order to see if there is a contribution of these rivers on the Seine River. Particle number concentration in the Seine River increases from upstream to downstream of Paris city for Ce and Ti. Indeed, 500,000 Ce-bearing part mL^{-1} and up to 1,350,000 Ti-bearing part mL^{-1} are measured at Marnay-sur-Seine, 96 km upstream Paris city. The highest particle concentration was found in the Marne River, a tributary of the Seine River, with 1,600,000 part mL^{-1} for Ce and 6,000,000 part mL^{-1} for Ti. This has an impact downstream the confluence between the Seine and the Marne rivers where the particle number concentration increases near Paris sampling point (1,400,000 part mL^{-1} for Ce and 4,700,000 part mL^{-1} for Ti). The next increase was observed near a water treatment plant (Bougival) with 1,200,000 Ce-bearing part mL^{-1} and 4,600,000 Ti-bearing part mL^{-1}, after Argenteuil sampling point (11 km downstream of Paris city). FEG-SEM imaging shows that particles containing Ce and Ti can be found in the suspended matter of the Seine River water. The size of detected particles varies from 200 nm to 5 μm. To further investigate the origins of NPs, elemental ratios of Ce/La and Ti/Al also need to be studied. 1. Gottschalk *et al*. 2013 ; 2. Mitrano *et al*. 2012

Wildlife ecotoxicology: from food chain exposure to population effects

382

Effects of Pb exposure on sperm quality and reproductive output of red-legged partridge

N. Vallverdu-Coll, IREC / Wildlife Toxicology; C. Castaño, INIA National Institute for Agricultural and Food Research and Technology; F. Mougeot, C.S.I.C; M.E. Ortiz-Santaliestra, J.J. López-Perea, IREC; J. Rodríguez-Estival, University of Calgary / Ecosystem and Public Health; J. Santiago-Moreno, INIA National Institute for Agricultural and Food Research and Technology; R. Mateo, U.C.L.M.-C.S.I.C. / Instituto de Investigacion en Recursos Cinegeticos

Lead (Pb) poisoning by the ingestion of shot pellets, bullet fragments or fishing weights is a frequent cause of death in wild birds, but also have a wide range of sublethal effects. Here we report on the effects that a sublethal Pb exposure during the prelaying period have on the breeding performance of red-legged partridges (*Alectoris rufa*). We studied separately the effects of exposing males or females on egg properties, laying performance, reproductive success, levels of dietary antioxidants and carotenoid-based coloration. We also studied the effects of male exposure on sperm quality and the relationship between sperm quality, carotenoid-based ornaments and antioxidant levels. We show that the prelaying Pb exposure induced the production of heavier and larger eggs, heavier chicks and reduced hatching success when females, but not males, were exposed. Fecundation rate and other laying performance parameters were unaffected. In males, Pb exposure decreased acrosomal integrity and sperm motility, and increased sperm vigour, but did not affect sperm viability, concentration or overall progress. Moreover, clutch size was increased in pairs in which the male had been exposed to Pb in comparison to unexposed pairs. Pb exposure increased levels of circulating antioxidants in males, whereas the percentage of eye-ring area pigmented by carotenoids decreased in exposed females. Overall, the sublethal Pb doses used here did not induce spermatozoon death or infertility in males, but rather caused an increase in reproductive investment. Pb exposed females also exhibited increased investment in reproduction, laying larger and heavier eggs and chicks, but had reduced carotenoid-based coloration and hatching rate. Several sperm parameters showed positive relationships with carotenoid-based coloration and levels of antioxidants that were influenced by Pb exposure, suggesting that redder males may be more capable to preserve sperm from oxidative stress.

383

Mercury trends in seabird eggs from Pacific Canada, 1968-2012, and relationships with stable isotopes

K.H. Elliott, McGill University; J.E. Elliott, Environment Canada / Science Technology Branch

Seabird eggs are used to monitor environmental mercury because they are relatively easy to collect and integrate a signal from the entire food web. Trends in mercury from seabird eggs, however, may represent variation in diet rather than variation in mercury availability; due to biomagnification, seabirds switching to feed at a higher trophic level will usually have higher mercury levels. We measured mercury concentrations in eggs from six seabird species in Pacific Canada during the period 1968-2012. In contrast to expectation, storm-petrels feeding partially on invertebrates had the highest mercury burden while herons feeding on large fish had the lowest mercury burden. Rather than correlating with trophic level (δ^{15}N), mercury levels correlated with δ^{34}S ($R^2 = 0.86$). For cormorants, the only group showing a significant temporal mercury trend, both mercury and δ^{34}S decreased over time. Sulfate-rich environments (high δ^{34}S) are occupied by sulfate-reducing bacteria that produce methylmercury, and we hypothesize that variation in mercury within and among seabirds is associated with variation in methylmercury production by sulfate-reducing bacteria at the base of the food web. Variation in mercury levels in seabirds across space and time were associated with the origin of sulfur in the diet.

384

Contamination of four ivory gull (Pagophila eburnea) colonies in Svalbard in link with their trophic behaviour

M. Lucia, H. Strøm, Norwegian Polar Institute; P. Bustamante, Université de La Rochelle / LIttoral ENvironnement et Sociétés LIENSs; D. Herzke, Norwegian Institute for Air Research NILU; G.W. Gabrielsen, Norwegian Polar Institute

The ivory gull is a high-Arctic species that spends the entire year closely associated with sea ice. This species is considered endangered in most parts of its breeding range. Ivory gulls must indeed cope with not only the reduction of sea ice cover triggered by climate change but also increasing contaminant loads due to changes in global contaminant pathways and the release of previously stored pollutants from melting snow and ice. In this context, the main objective of this study was to assess the trophic behaviour of this species in four colonies located

on Barentsøya, Svalbard, and the relationship between contaminant exposure and its diet. Contaminants, encompassing a number of organochlorines (OCs), brominated flame retardants (BFRs), and perfluorinated alkyl substances (PFASs), were determined in the blood (plasma and whole blood) of ivory gulls collected over several years. In parallel, carbon and nitrogen stable isotopes were determined in different tissues (feathers, plasma and red blood cells, or whole blood) to infer the trophic level ($\delta^{15}N$) and feeding habitat ($\delta^{13}C$) during both the breeding and the moulting periods. The most quantitatively abundant contaminants found in the ivory gull were *p,p'*-DDE (dichlorodiphenyldichloroethylene), ΣPCB (polychlorobiphenyl) and PFOS (perfluorooctane sulfonate). Ivory gulls demonstrated changes in the diet between the breeding and the moulting periods. The moulting period was characterized by enriched $\delta^{13}C$ and $\delta^{15}N$ signatures which suggest a more oceanic foraging location and a higher trophic position. This study also highlighted the same feeding habitats and strategies amongst ivory gull's breeding sites. The lack of differences in feather signatures between colonies could reflect either that birds from Barentsøya mainly come from the same migrating routes, or that they maintain the same diet independently of their wintering area. Several compounds including most of the PFASs, *trans*-nonachlor, *cis*-nonachlor, and BDE-28 demonstrated their biomagnification potential in the ivory gull food web. Overall, the levels of OCs, BFRs and PFASs did not suggest direct lethal exposure to these compounds but their potential synergetic or additive sublethal effects warrant continued monitoring.

385

Development of Sublethal Thresholds and Toxicity Reference Values to Examine the Risk of Brodifacoum to Raptors

B.A. Rattner, USGS-Patuxent Wildlife Research Ctr / Beltsville Lab; K. Horak; J. Lankton, USGS-National Wildlife Health Center; R. Lazarus, USGS Patuxent Wildlife Research Center / USGS; J.J. López-Perea, Spanis Institute of Game and Wildlife Research / CSICUCLMJCCM; T.G. Bean, University of Maryland / Department of Environmental Science and Technology

On a global scale, brodifacoum continues to be one of the most widely used anticoagulant rodenticides for control of vertebrate pest species. Its toxicity and risk to non-target raptorial and scavenging birds is well-documented. While numerous exposure and toxicity studies have been conducted in owls (Stringiformes), its toxicity in other raptors (Falconiformes) in controlled exposure studies is less-well described. American kestrels (*Falco sparverius)* were provided daily access to two 25 g meatballs (Nebraska Bird of Prey diet) containing vehicle (control) or brodifacoum at nominal concentrations of 0.3, 1 or 3 ppm wet weight for 7 days (N=5 birds/group). These nominal brodifacoum concentrations were analytically verified (90.3-101.0% recovery), and are similar or less than carcass and liver concentrations (i.e., ~ 3 μg/g and ~18 μg/g, respectively) found in target rodents following eradication operations. Uneaten food scraps were collected daily, kestrels were observed twice each day, and weighed and examined at various intervals. After 7 days of exposure, a jugular blood sample was drawn into a syringe containing sodium citrate. Hematocrit was determined and plasma was frozen for clotting time assays. Birds were euthanized, necropsied and various tissues were fixed in phosphate-buffered formalin for histopathological evaluation. Neither food consumption nor body weight differed significantly among groups. Overt signs of intoxication (bruises on featherless tract, evidence of bleeding) and some microscopic hemorrhages were apparent at dietary concentrations of 1 and 3 ppm. In comparison to controls, hematocrit was reduced ($P< 0.05$) by ingestion of 1 and 3 ppm brodifacoum, with some birds being classified as anemic (hematocrit < 30). Prothrombin time and Russell's viper venom time were both prolonged ($P< 0.05$) in all groups receiving brodifacoum. Using data on daily brodifacoum consumption and classification of an exposed kestrel as being anemic, toxicity reference values (TRVs) were generated. The dietary-based TRV at which 50% of exposed kestrels exhibited anemia was estimated to be 246 μg brodifacoum consumed/kg kestrel body weight-day and 2.62 mg brodifacoum consumed/kg kestrel body weight-week. These TRVs are below environmental concentrations that might be encountered by free-ranging raptors consuming rodent following an eradication effort, and quantitatively document the hazard of brodifacoum to non-target birds of prey.

386

Balance between ecological interactions and chemical exposure on food-chain dynamics

V. Baudrot, Université Bourgogne Franche-Comté; C. Fritsch, CNRS / UMR ChronoEnvironnement; A. Perasso, Université de Franche Comté UMR CNRS; M. Banerjee, IIT Kanpur / Department of Mathematics and Statistics; F. Raoul, University of Franche-Comte / UMR UFCCNRS

In this study, we develop an ecotoxicological model based on a system of differential equations designed to predict the population dynamics of a terrestrial one-prey one-predator food chain exposed to metal contaminants. Biological models are small mammals, a raptor the barn owl, and cadmium (Cd), a persistent contaminant. We use our model to test different exposure scenarios of the predator according to prey trophic position (herbivorous, carnivorous or omnivorous). Contaminants, as the Cd, affect the survival and the reproduction abilities of exposed individual prey and predator, and therefore change the classical predator-prey dynamics. Analytical results show a general pattern where cyclic dynamics are observed at low concentration of Cd in soil, and then, the increase of Cd stabilizes populations dynamics. When the concentration of Cd increases, the model may have two stable steady points meaning that a subtle change in the initial conditions (initial prey and predator densities) implies totally differents steady states (predator-prey coexistence or extirpation of the predator). At higher contaminant concentration in soil, the biomagnification process extirpates the predator population what releases the predation pressure on preys and allows their increase. Finally, at high concentration, both prey and predator species collapse. The comparison of several prey species differentiated by their diet from herbivorous to carnivorous induces different patterns of predator exposure, and therefore change the dynamics of the entire food-chain. The results obtained from this food chain model illustrates the importance of cascades effects, that is indirect effect modulated by trophic relationships. For instance, the model reveals the occurrence and position of tipping point (bifurcation) where a subtle change in conditions causes a sudden change in the ecological system. The exploration of the tipping point behaviors with a mathematical bifurcation analysis allows to measure the impact of a change in prey resources (bottom-up cascade effect) or in the apex predator abundance (top-down cascade effect). As a consequence, this simple food chain model can help to identify populations that are critical for transfering adverse effects of contaminants across trophic levels. The direct next step of this work is the incorporation of multi preys though the use of multi-species functional responses to model the prey-selection behavior of the top predator.

Mechanistic effect modelling for risk assessment: state of the art, applications, use in a regulatory context and future directions (II)

BEEHAVE model evaluation according to Good Modelling Practice

F. Streissl, EFSA / Pesticides Unit; M. Arena, EFSA - European Food Safety Authority / Pesticides; J. Boesten, Alterra / ERA team; F. Hatjina, Division of Apiculture, Inst. of Animal Science, Hell. Agr. Org.DEMETER,; A. Rortais, EFSA / Scientific Committee and Emerging Risks Unit Department of Risk Assessment; F. Sgolastra, Dipartimento di Scienze Agrarie, Università di Bologna; R. Smith, School of Applied Sciences, University of Huddersfield; C. Szentes, EFSA - European Food Safety Authority / Pesticides Unit; C.J. Topping, Aarhus University / Department of Bioscience

Rapid scientific progress has been made in recent years in ecological modelling. Workshops such as Lemtox and MEMORISK have explored the use of ecological models in pesticide risk assessment. Industry has submitted models to address specific risk assessment questions. However, the lack of guidance on the evaluation of models has been a major hurdle for using them in a regulatory context. In order to facilitate the evaluation (and the development) of regulatory ecological models EFSA issued an opinion on good modelling practice[1] or GMP. The GMP approach was first applied in the EFSA PPR panel statement [2] to evaluate BEEHAVE [3], a comprehensive individual based model simulating honeybee colonies that was published in 2014 (http://beehave-model.net/). The BEEHAVE model fulfilled most of the criteria outlined in the GMP opinion [1]. It was concluded that the model is not yet usable in a regulatory context or to address the risk from multiple stressors at the landscape level. Recommendations for further developing the model in order to address these questions are, for example, the development of a pesticide module, adding additional biological agents such as infectious agents, pests and predators and interactions between those agents and the landscape (including critical beekeeping practices, climate, weather and landscape characteristics).The supporting data and default parameter values should be further evaluated and justified. The PPR Panel recommends adopting the model as the basis for modelling the impact on honeybee colonies of pesticides and other stressors. Further development might require a different programming language, for example a standard object-oriented language.

388

The honeybee model BEEHAVE: current status and future developments

V. Grimm, Helmholtz centre for environmental research - UFZ / Department of Ecological Modeling; M.A. Becher, The University of Exeter / Environment Sustainability Institute; J. Horn, Helmholtz centre for environmental research - UFZ; P.J. Kennedy, J.C. Rumkee, J.L. Osborne, The University of Exeter / Environment Sustainability Institute

The honeybee model BEEHAVE was developed to explore the influence of various stressors on colony health and survival. The main stressors represented are limitations in forage, diseases transmitted by varroa mites, and pesticide-induced mortality of in-hive bees or foragers. An expert working group at EFSA evaluated in great detail the suitability of BEEHAVE for regulatory risk assessment. Because of this potential of and interest in BEEHAVE, we here summarize the state of the art regarding BEEHAVE and outline possible future developments. BEEHAVE was used to (1) explore the effects of forage gaps and (2) pesticide-induced mortality on colony survival. Forage gaps of two weeks in June or July are most detrimental. Increased mortality of adults affected colony survival much more than pesticide effects on the brood or egg-laying. EFSA considered the representation of honeybee colony dynamics and foraging suitable, but would require a specific pesticide module and an easier representation of different landscape before BEEHAVE can be used in regulatory risk assessment. We conclude that BEEHAVE is a milestone towards using mechanistic effect models for risk assessment for honeybees, but further model tests, refinements, and possibly a re-implementation are needed.

What can we learn from robustness and sensitivity analysis of an individual-based Collembola model for risk assessment?
V. Roeben, RWTH Aachen University, Institute for Environmental Research / Institute for Environmental Research BioV; M. Ross-Nickoll, RWTH Aachen / Institute for Environmental Research BioV; A. Schaeffer, RWTH Aachen University / Institute for Environmental Research; T. Preuss, Bayer CropScience / Environmental Modelling
With respect to environmental risk assessment it is crucial to know where and when to protect an organism but still little is known on the vertical dispersal and seasonal fluctuations of collembolan communities in agricultural landscapes. To overcome this lack of knowledge, we developed an individual-based model of the soil-dwelling collembolan *Folsomia candida*. The model FOLCAS (Folsomia candida simulation) is a vertical distribution model in an agricultural soil column, which can be applied to demonstrate the effect of variations in environmental parameters on the population and its dispersal. In addition, the model features the option to evaluate the effect of a pesticide application. In this study we will present the results of the first robustness analysis and sensitivity analysis of the model FOLCAS. We will use the findings to improve the model, but also to learn about their possible impact on the current risk assessment of non-target arthropods. It is assumed that the model reflects the major environmental processes. Thus, the sensitivity analysis allows us to review the hypotheses of influencing factors on the collembolan movement and hence its possible exposition to a plant protection product within the field. The method of sensitivity analysis not only enhances the understanding of the model, but it can also highlight the important processes and parameters, which are crucial to establish a more realistic environmental risk assessment for soil-dwelling collembolans. Once identified, these sensitive processes and parameters need further attention in order to reduce the uncertainty of the risk assessment. Parameters or processes identified as insensitive for the system can be assumed less important, where even high insecurities will not lead to a high uncertainty of the risk assessment.

390
A model-based method to analyze ecotoxicology experiments in mesocosm
C. Leloutre, INERIS / Models for Ecotoxicology and Toxicology METO; A. Péry, INRAAgroParisTech; R. Beaudouin, INERIS / Models for Ecotoxicology and Toxicology METO
The mesocosms (experimental ecosystems) improve the ecological relevance of the studies on the effects of xenobiotics on aquatic species. However, in mesocosm studies, the number of replicates is limited by practical and financial constraints. In addition, high levels of biological organization are characterized by a high variability of descriptive variables. This variability and the poor number of replicates have been recognized as a major drawback for detecting significant effects of chemicals in mesocosm studies. These characteristics induce a large uncertainty on the probabilistic distributions of the endpoints (location parameter, variability and shape) in mesocosm experiments. To reduce this uncertainty, a solution would be to optimize the knowledge used to define the expected probabilistic distribution of the endpoints for a given experiment in control conditions. A way to combine all the information available is to develop, calibrate and validate a model of for the population studied in mesocosm. This model will be fed by the characteristics of a given experiment (initial points, environmental *scenario*), the characteristics of the species that was chosen (ethology, ecology, population dynamics) and the characteristics of the experimental system (for example species composition of the mesocosm). We evaluated here this methodology on experiments conducted in lotic mesocosm and focused on the three-spined stickleback (*Gasterosteus aculeatus*)population dynamics. An individual based-model (IBM) was developed from a bioenergetic model following the Dynamic Energy Budget theory in order to represent the life-cycle of sticklebacks (DEB model). Sensitivity analyses were performed to explore the DEB-IBM, and the parameters of the model were adjusted using two dataset with two different environmental *scenarii*. The predictability of the model was then tested using two other datasets. Finally, we observed on a case-study that mesocosm data analysis was improved by using the model-based methodology proposed. To conclude, designing an individual-based model is very promising for improving mesocosm data analysis.

391
Modelling the impact of herbicides on phytoplankton for relevant ecological scenarios of varying complexity
T. Strauss, Research Institute gaiac / Research Institute Gaiac; E. Bruns, Bayer CropScience AG / BCS D ETX Ecotoxicology; J. Witt, Bayer CropScience; T. Preuss, Bayer CropScience / Environmental Modelling
Mechanistic effect models (MEMs) are useful tools for ecological risk assessment of chemicals. The most important recommendations of the SETAC MODELINK workshop are that the models should be as realistic as possible for a specific risk assessment question, and the level of conservatism required for a specific risk assessment should be reached by designing appropriately conservative environmental and exposure scenarios. As for aquatic invertebrates, phytoplankton algae have to be protected at the population level by considering their abundance/biomass in edge-of-field surface waters [EFSA AGD]. Especially for the ecological recovery option (ERO), all relevant processes that determine population viability and the propagation of effects on the community-, ecosystem- and landscape-level must be considered. As defined in the EFSA AGD the reference tier for algae are micro-/mesocosms including competition, predation and natural stressors. According to these requirements, aquatic algae should be modelled as populations within an ecosystem modelling framework. The main question to be addressed is the level of complexity which is needed for a realistic and accurate description of population dynamics. In this presentation, we will introduce an ecosystem model framework for quantifying responses to stress at different levels of ecological complexity for freshwater algae in standing waters. We use a complex biogeochemical lake model (StoLaM) to predict population dynamics of phytoplankton species under realistic field conditions taking into consideration growth rate inhibition as the toxic mode of action. StoLaM's modular structure enables us to simulate a wide range of ecological scenarios from laboratory conditions (one algal species, constant temperature and light conditions) to high ecosystem complexity with several competitors, trophic levels and dynamic physico-chemical and weather conditions. Our aim is to develop ecological scenarios of increasing ecosystem complexity using StoLaM, and to evaluate these scenarios under different exposure and climatic conditions with respect to the sensitivity of the phytoplankton.

392
Simulation of Exposure, Bioaccumulation, Toxicity and Estimated Productivity Losses from the Deepwater Horizon Oil Release in the Mississippi-Alabama Nearshore Marine Environment
E. Blancher, Moffatt & Nichol; J.S. Clough, Warren Pinnacle Consulting, Inc.; R.A. Park, Eco Modeling; S.P. Milroy, University of Southern Mississippi / Department of Marine Science
The Deepwater Horizon (DWH) incident provided an opportunity to develop the mechanistic model, AQUATOX 3.1 Nearshore Marine Environment (NME), to estimate impacts from this event. Oil exposure followed the generally accepted conceptual framework that the oil rapidly coursed across the surface of the water column towards the shoreline with mixing by winds, waves and currents. This relatively short-lived water column event was followed by a subsequent pulse of contaminants, primarily various PAHs, which became re-entrained in the detrital and sediment pools within the nearshore coastal environment. The PAHs were then diluted by advection and various degradation processes and were taken up by the food chain, as was borne out by the available data collected during and after the incident. We present our approach, using the AQUATOX 3.1 NME modeling framework, to analyze this oiling event with water-column exposure followed by a longer-lived sediment exposure to the food chain. Exposure to nearshore coastal habitats uses maximum-likelihood estimates of various scenarios of oil concentrations. The octanol-water equations for partitioning of PAHs in the water column (dissolved and various combined forms) within various PAH "bins" are presented. Using AQUATOX 3.1 NME, we then predict subsequent uptake and bioaccumulation of the PAH bins within various biotic groups and predict resulting toxicity. Observations of water, sediment, and biota available through the natural damage assessment and other published sources are used to verify the model predictions. From this exposure and the subsequent toxicity we have estimated overall productivity losses at several trophic levels across various habitats within the nearshore Mississippi-Alabama coast.

Quantitative in vitro to in vivo extrapolation (QIVIVE): Advances in tools to quantify exposure (dose)-response relationships and use in risk assessment

393
Building improved in-vitro exposure assessment capability: Towards the development and implementation of enhanced QIVIVE tools
T. Gouin, Unilever / Safety and Environmental Assurance Centre; J.A. Arnot, ARC Arnot Research & Consulting / Department of Physical Environmental Science; M.R. Embry, ILSI Health & Environmental Sciences Institute (HE
Risk assessment is generally divided into human health risk assessment (HRA) and environmental risk assessment (ERA). For instance, scientific research, policy discussions, and regulatory instruments for HRA and ERA are addressed by individuals with different sets of expertise and knowledge, oftentimes at different institutes, research organizations, and government agencies. Integration of HRA and ERA, however, could provide substantial benefits, particularly by providing a more efficient framework on which to address emerging problems and questions that have the potential to impact both the environment and human society. Society is facing a variety of challenges; growing concerns about the effects of multiple

stressors (both chemical and non-chemical); risks associated with exposure to complex mixtures; and demands to quantify local site-specific risks. Integration of HRA and ERA could thus lead to more scientifically sound assessments by combining cross-discipline expertise and data, lowering costs and reducing the time needed to improve quantification of risks. A key challenge, however, in advancing our understanding between toxicological effects and exposure concentrations is the need for improved tools to measure and control the freely dissolved concentration of a chemical, particularly in an *in vitro* test system. Current practice typically relates results obtained from an *in vitro* test system to a nominal concentration, which acts as a surrogate in establishing exposure-response relationships. However, depending on the physicochemical properties of a chemical, substantial variability between the nominal and the freely dissolved concentration might exist. Characterizing uncertainty related to the difference between the nominal and freely dissolved concentration is necessary to advance our understanding of integrating hazard and exposure information. This also represents a challenge of quantitative *in vitro*-to-*in vivo* extrapolation (QIVIVE) tools, which are necessary to enhance the development of mechanistic physiologically based pharmacokinetic (PBPK) models. This presentation will explore research needs related to quantification of the key processes influencing the exposure-response relationship in a variety of *in vitro* test systems. The objective is to help prioritize research needs that will address the limitations associated with improved quantification of in vitro to in vivo extrapolation.

394

Examining underlying assumptions when translating in vitro bioassay results to in vivo conditions

J.A. Arnot, ARC Arnot Research & Consulting / Department of Physical Environmental Science; J.M. Armitage, University of Toronto - Scarborough / Physical and Environmental Sciences; M. Embry, ILSI; T. Gouin, Unilever / Safety and Environmental Assurance Centre

There is a paucity of measured toxicity data compared to the large number of chemicals and endpoints required for chemical hazard assessment. Emerging alternative test methods are being developed and evaluated to reduce and eliminate unnecessary animal testing. Cell-free and cell-based in vitro systems are being developed and applied for hazard and risk assessment. For human health assessment nominal concentrations from these in vitro assays are commonly assumed to be equivalent to steady-state blood concentrations in vivo. These steady-state blood concentrations are then used to calculate oral equivalent doses (OEDs) that can then be compared against exposure intake rates for risk-based prioritization. Here we use in vitro mass balance models and equilibrium partitioning theory to examine differences in the dissolved chemical concentration corresponding to the assumed nominal (administered, unmeasured) chemical concentration from an in vitro assay for a range of chemical partitioning properties and in vitro assay conditions. We compare the in vitro concentrations to in vivo blood concentrations and illustrate how the data can be interpreted differently. Finally, we apply the chemical activity approach in the data analysis as a means to clarify data interpretation and translation across systems (i.e., in vitro to in vivo). Implications for hazard and risk-based ranking are discussed.

395

Bioavailability of organic micropollutants in cell-based bioassays

F.C. Fischer, Hemholtz Centre for Environmental Research - UFZ / Cell Toxicology; K. Goss, Helmholtz centre for environmental research - UFZ / Analytical Environmental Chemistry; A. Jahnke, Helmholtz Centre for Environmental Research UFZ / Cell Toxicology; M. Krauss, Helmholtz centre for environmental research - UFZ / Effect Directed Analysis; B.I. Escher, Helmholtz Centre for Environmental Research UFZ / Cell Toxicology

In vitro bioassays are generally complex heterogeneous systems, and differences in chemical distribution are recognized as important issues concerning *in vitro* bioavailability. The freely dissolved concentration is generally considered as responsible for biouptake and can be reduced by sorption to medium compartments, biomaterial and plate material as well as evaporation and degradation. Consequently, the nominal concentration is often not an adequate metric to describe exposure and characterize toxicity. Our approach is to apply and experimentally validate a full mass balance model to different cell-based bioassays covering various toxicity pathways and a selection of non-volatile priority chemicals. We will then use the model to link observed toxicity directly to modelled bioavailability. The first stage of the model is based on equilibrium partition constants, with kinetic processes, such as degradation and diffusion into plate material excluded. We collected partition constants from the literature or used Quantitative Structure-Activity Relationships and other models for prediction. Bovine serum albumin and liposomes (membrane lipid bilayer vesicles) served as surrogates for proteins and lipids in the test medium and cells. The protein and lipid concentrations in the medium and cells were measured. Chemicals with low hydrophobicity were predicted to be predominantly freely dissolved and thus bioavailable. With increasing hydrophobicity, the fraction of chemicals bound to proteins and lipids increased strongly, with fractions of freely dissolved chemicals < 0.1 % for chemicals with a log K_{ow} > 6. These results demonstrate the deficiency of using nominal concentrations to characterize toxicity, in particular for hydrophobic chemicals, whereas correcting effect concentrations by modelled freely dissolved and cellular concentrations can lead to higher significance and comparability of toxicity data. We aim to improve the accuracy of the model in the near future. For this purpose, partition constants for chemicals with diverse physicochemical properties to medium compartments and cells will be measured. We will optimize and generalize the bioassays to which the model will be applied and produce empirical data on medium composition and structure of the respective cell lines. Furthermore, time-dependent processes like diffusion in plate materials, degradation, cell-uptake and growth dilution will be considered.

396

Getting biotransformation kinetic parameters as a bonus out of bioaccumulation experiments

D. Kuo, City University of Hong Kong / Architecture and Civil Engineering; C.C. Chen, City University of Hong Kong / Department of Architecture and Civil Engineering

Biotransformation is one of the important processes that can influence the fate of contaminants in living organisms. To properly understand the contribution of biotransformation, the *in vivo* metabolic rate constant, k_M, needs to be determined. Despite its importance, k_M has remained one of the least understood (in terms of modeling) and one of the most hard-to-get parameters. Two major approaches are currently and commonly used to determine k_M: by *difference* and by *experiment*. The *difference* approach derives k_M by subtracting the contributions from growth (k_G), egestion (k_E), and out-going transport from the biota (i.e., k_2) from the total depuration constant (k_T). While this approach has been successfully applied, leading to the development of k_M database (e.g., Arnot et al. 2008 ET&C 27:341-351), it has the occasional problem of producing negative k_M's. The *experiment* approach, while preferred in principle over the *difference* method, suffers from a lack of mathematical tools to properly delineate k_M from the observable quantities. Furthermore, it is often complexed with experimental constraints intrinsic to standard bioaccumulation procedures or practices. We proposed a generic protocol, developed a set of mathematical models, and devised a scenario map to address the need for determining k_M experimentally. Equations were constructed from first principle following the established first-order kinetic framework for different exposure and accumulation scenarios. The developed approach allows k_M of the parent compound (PC) to be determined from the kinetic measurements of its metabolites (MBs). The protocol and the scenario map were applied to and successfully validated using data from studies where PC and MB kinetic data were reported. This study ended with recommendations on how bioaccumulation of contaminants in living organisms may be experimentally investigated to reduce resource, effort, and data-reduction complexity while getting accurate toxicokinetic properties of the contaminant. Our message is that k_M's can be easily determined as a "bonus" if bioaccumulation experiments and data reduction are done right.

397

Mapping risk assessment challenges for HPC ingredients: a chemical space analysis

C. Rendal, O. Price, Unilever / Safety and Environmental Assurance Centre SEAC; T. Gouin, Unilever / Safety and Environmental Assurance Centre

The inclusion of chemical ingredients in Home and Personal Care (HPC) products is based onthe functionality that their individual physicochemical properties bring towards enhancing the overall performance of the product. Given the broad range of functions that HPC products provide (cleansing, moisturizing, conditioning, etc), chemical ingredients used in these products can therefore capture a broad range of chemical classes, for instance from being extremely hydrophilic to extremely hydrophobic, neutral organics, inorganics, ionisable, and permanently charged salts. As it happens, not only do the physicochemical properties of various chemical ingredients influence the functionality of a HPC product, they also influence the behaviour and fate in test systems (*in vitro*, *in vivo*, and *in silico*) and in the environment. It is thus critical that the physicochemical properties be considered in both experimental design and selection of appropriate in silico tools. Using an example from industry, we examine the chemical space of a selection of HPC ingredients (>7000) and discuss implications towards assessing behaviour *in vitro*. We base our analysis on batch estimates of chemical properties (using SMILES strings), and discuss the validity of such estimates for the chemicals in question. We filter the chemicals using a set of basic criteria to identify groups of chemicals for which standard risk assessment procedures are not applicable. This analysis provides a comprehensive overview of the specific modelling and laboratory research challenges that risk assessors face in dealing with HPC ingredients.

398

Regulatory Integration of In Vivo and In Vitro Toxicity Information: A Perspective on the Extent of the Challenge

L.S. McCarty, L.S. McCarty Scientific Research & Consulting; J.M. Armitage, University of Toronto - Scarborough / Physical and Environmental Sciences

Formulating regulatory exposure levels for environmental media on a chemical-by-chemical basis has been successful. However, changes in emphasis - reducing test animal usage, focusing on much larger numbers of chemicals, and addressing multiple media and species - require a more efficient regulatory paradigm and more testing data. Alternative approaches being considered involve generating large amounts of *in vitro* toxicity data, then linking changes in biochemical processes through levels of biological organization (LBO) to whole organism adverse apical effects and beyond – populations, communities, and ecosystems. As toxicological understanding improve proponents aspire to move from *in vivo* toxicity testing prioritization to supplantation. New paradigm challenges, and recommendations to address them, are reviewed in four areas. Firstly, dose-response difficulties. Bioavailability is an important confounding influence, affecting the dose surrogate chain from external exposure through whole organism then organism subcompartments to the subcellular site(s) of toxic action. Additionally, solvents used in most *in vitro* testing protocols have an unquantified bioavailability influence that can act as a toxicity modifying influence. Secondly, there many toxic action identification/classification schemes. However, there is no holistic, phylogenically-relevant (human/mammalian and environmental; i.e., plants and bacteria through fish to birds), broadly applicable, widely accepted scheme for identification, classification, and relative potency estimation for either modes/mechanisms of toxic action or adverse outcome pathways (AOP). Thirdly, in the LBO concept new properties that emerge from translevel integration of lower level properties are not necessarily predicable. Thus, it is difficult to establish single direct deterministic causal links through multiple LBO levels. Effects observable at upper LBO levels may be induced by multiple unrelated initiating events occurring at lower LBO levels. Also, *in vivo* toxicology is a “middle-out” approach with an inordinate focus on tests whose outcomes are for narrowly defined statistical populations poorly linked to higher LBO. Fourthly, is the largely neglected issue of primary validity and task-specific relevance for both *in vivo* and in vitro toxicity testing data. Use of accepted testing methods is not a guarantee of validity or relevance and weight-of-evidence (WOE) schemes rarely address either adequately.

Epigenetic and evolutionary effects of pollutants: new challenges for long-term ERA

399

Integration of Epigenomics in Systems Toxicology

L. Navarro-Martin, Institute of Environmental Assessment and Water Research / Department of Environmental Chemistry; E. Ortiz, M. Casado, L. Herrero-Nogareda, Institute of Environmental Assessment and Water Research IDAEA-CSIC / Department of Environmental Chemistry; L. Peñarrubia, J. Viñas, Universitat de Girona; R. Tauler, Institute of Environmental Assessment and Water Research IDAEA-CSIC; B. Pina, IDAEA-CSIC / Department of Environmental Chemistry

Increasing evidence demonstrates that environmental insults occurring during early development may have life-long effects, indicating that epigenetic mechanisms could be involved. However, epigenetic approaches in ecotoxicology are still lacking. Therefore, we engaged in a study to evaluate the effects of Endocrine Disruption Chemicals (EDCs) on zebrafish development by combining transcriptomics and epigenomics. Applying Next Generation Sequencing (NGS) technologies, we aimed to: 1) recognize target genes regulated by EDC exposures at the transcriptomic and epigenomic level; 2) develop new tools to characterize toxicity pathways and identify epigenetic biomarkers; 3) integrate transcriptomic and epigenetic platforms to identify whole genome molecular footprints characteristic of EDCs exposures. Due to its similarities in epigenetic regulatory machinery to mammals, the zebrafish is a recognized model for the analysis of epigenetic mechanisms in developmental biology and in environmental epigenetics. Our long-term target is the fusion of multiple omic techniques to identify models to predict phenotypic traits and outcomes. For example, the simultaneous determination of expression patterns by RNA-sequencing (RNA-seq) and differentially methylated genes by DNA Immunoprecipitation sequencing (MeDIP-Seq) allows the study of epigenetic effects at different levels and the identification of new pathways that might not be clearly identified by the separate analysis of the two data sets. Results presented here will provide a unique possibility to increase the understanding of the new field of ecotoxicoepigenomics and will exert a positive influence in the study of the effects of emerging contaminants in the genome as a whole. This study will increase the knowledge of regulatory mechanisms and modes of action of EDCs at a global scale, including epigenetic effects. Downstream analysis such as DNA motif discovery or the prediction of protein function could be proposed in the future to uncover potential modes of action. We anticipate that studies on ecotoxicoepigenetics will assist in early detection and risk assessment of environmental emerging contaminants in the near future.

Differential DNA methylation following mono(2-ethylhexyl)phthalate and 5-azacytidine exposure in zebrafish.

j. kamstra, NMBU / BaSam; L. Bastos Sales, VU University Amsterdam / Institute for Environmental Studies IVM; P. Cenijn, Vrije Universiteit Amsterdam / Institute for Environmental Studies; M. den Broeder, J. Koning, VU University Amsterdam / Institute for Environmental Studies IVM; P. Aleström, Norwegian University of Life Sciences / Basic sciences and aquatic medicin; J. Legler, Vrije Universiteit Amsterdam / Institute for Environmental Studies

Recent rodent studies demonstrating environmentally induced transgenerational epigenetic effects linked to increased disease risk have drawn much attention. Some of those studies observed changes in the DNA methylome indicating that effects can be inherited via DNA methylation. However, most of these studies use high concentrations and some results cannot be replicated in follow up studies. Clearly, more research is needed to understand the basic mechanisms encompassing transgenerational epigenetics. Here, we used a transgenerational set up using zebrafish as a vertebrate model organism to investigate the acute, latent and transgenerational effects on gene expression and DNA methylation of early life exposure to the putative obesogenic phthalate metabolite mono(2-ethylhexyl)phthalate (MEHP) and the DNA methylation inhibitor 5-azacytidine (5AC). We exposed zebrafish from 0 to 6 days post fertilization (dpf) at concentrations, which did not cause embryotoxicity (30 and 10 μM for MEHP and 5AC, respectively). We analyzed the expression of 41 obesity related genes, performed global (hydroxy)methylation analysis and genome wide DNA methylation analysis (reduced representation bisulfite sequencing) in F0 6 dpf larvae. Analysis of gene expression and global methylation in F0 larvae (15 dpf) and adults (brain, gonads) as well as F1 and F2 embryos is currently underway. In addition, we performed bisulfite amplicon sequencing on 10 differentially methylated regions (DMRs) discovered by the genome wide methylation analysis. Our results show a high number of genes (18 out of 41) were differentially expressed at 6 dpf, but only two of those genes were differentially expressed at 15 dpf following MEHP exposure. Subsequent analysis is ongoing. Genome wide DNA methylation analysis revealed 148 and 311 DMRs for MEHP and 5AC, respectively. Ingenuity pathway analysis revealed enrichment in cancer development, gastrointestinal diseases and nervous system development with MEHP, as well as a significant enrichment of genes related to obesity. For 5AC, general stress responses and effects on embryonic development were enriched. Bisulfite amplicon sequencing is ongoing and will reveal whether selected regions are transgenerationally inherited. Our results reveal considerable effects on DNA methylation following exposures during early life in zebrafish to MEHP and 5AC at nontoxic concentrations. This study will provide new knowledge about transgenerational epigenetics in zebrafish.

401

Genetic and epigenetic modifications following parental exposure of the Pacific oyster, Crassostrea gigas, to the herbicide diuron: The GIMEPEC project

F. Akcha, IFREMER / Laboratory of Ecotoxicology; A. Barranger, IFREMER / Laboratory of Ecotoxicology Laboratory of Genetics and Pathology of Marine Molluscs; E. Bachere, IFREMER / UMR IHPE; A. Benabdelmouna, IFREMER / Laboratory of Genetics and Pathology of Marine Molluscs; J. Rouxel, IFREMER; R. Rondon Sallan, IFREMER / UMR IHPE; C. Cosseau, C. Grunau, University of perpignan / UMR IHPE; C. Heude Berthelin, University of Caen Basse Normandie / UMR BOREA; D. Piquemal, ACOBIOM; D. Menard, IFREMER / Laboratory of Ecotoxicology; C. Montagnani, IFREMER / UMR IHPE University of Montpellier; T. Burgeot, IFREMER / Department of Biogeochemistry and Ecotoxicology

Oyster production basins are located in coastal waters receiving pollutants from exoreic catchment area. Among them, pesticides such as herbicides are of concern as they are frequently detected and sometimes at high concentrations. As a consequence, there is a need to study their impact on oyster. As a matter of fact, recurrent oyster mortality outbreaks are observed worldwide, legitimating the suspicion of a possible impact of pollutants on its ability to face environmental stressors. That is the main goal of the GIMEPEC « Genotoxicity, IMmunotoxicity and rEprotoxicity of PEsticides in *Crassostrea gigas* » project that puts forward genetic alterations induced by herbicides as a basis for a potential decrease in oyster physiological performances. To investigate the parental effects of herbicides, genitors involved in gametogenesis were exposed to environmentally realistic pulses of diuron. At spawning, semen from each control and assay groups were recovered in order to produce the next generation. Among results, we first demonstrated the genotoxicity of diuron by the comet assay in the hemocytes of oyster genitors. Moreover, the oxidised DNA base 8-oxodGuo was also detected at higher levels in the gonads of genitors exposed to the herbicide. Immunohistochemistry analysis revealed the presence of 8-oxodGuo in all stages of germ cell line, explaining the detection of DNA damage in reproductive cells as well: in spermatozoa of exposed genitors a significantly higher level of DNA strand breaks was measured. The vertical transmission of diuron-induced DNA lesions was confirmed by flow cytometry analysis of offspring DNA. Both a clastogenic (chromosome breakage) and aneugenic (change in chromosome number) effect was detected following parental exposure to the herbicide. By using Fluorescent In Situ Hybridization, it was even possible to identify some of the damaged part of oyster genome. In parallel to this genetic modifications, parental exposure to diuron affected DNA methylation in the offspring. A BS-seq analysis allowed the identification of 235 differentially methylated regions corresponding to 169 genes. By comparing these results with those from RNA-seq, no clear relationship was however showed between methylation and gene expression. These modifications of the DNA were concommitally observed

with negative impacts on spat physiology in terms of reduced growth (reversible) and developmental abnormalities.

402
Field evidence of reproduction impairment through sperm DNA damage in the fish nase (Chondrostoma nasus) in anthropized hydrosystems
A. DEVAUX, INRA-CNRS / UMR LEHNA USC INRA IGH ENTPE; S. BONY, INRA-CNRS; S. PLENET, LEHNA CNRS; P. SAGNES, ONEMA; S. SEGURA, LEHNA CNRS; R. SANTOS, CEFE; M. NOVAK, LEHNA CNRS; A. GILLES, CNRS; J. OLIVIER, LEHNA CNRS
A clear trend for a worldwide decline of fish populations has been documented over the last decades in freshwater ecosystems. Among numerous potential causes, pollution pressure due to industrial, agricultural and urban activities is considered as one of the main factors responsible for this decline. Contaminants can affect fish reproduction through different mechanisms leading to endocrine disruption and/or to the impairment of embryonic development, hatching and larvae growth. Previous studies have demonstrated a linkbetween the integrity of sperm DNA and the quality of offspring development in fish and invertebrates. Present work aims to explore this relationship in the field as a possible cause of the decline through reproduction impairment of a feral fish population. Mature nase (*Chondrostoma nasus*) were caught during the breeding season in three locations (A, B and C) of the Rhône River basin and gametes were collected by stripping. Sampling locations were chosen according to the following gradient of contamination due to human activities on the watershed: A≤B< C. Samples of a pool of collected ovocytes were fertilized with the sperm of individual males and then incubated individually back to the lab to study embryo-larval development as well as sperm samples to assess DNA integrity. Genetic analysis clearly showed the absence of a difference in genetic structure between the three studied fish populations from the Rhône basin. Sperm DNA integrity was significantly lower in males from station C compared to other ones when sperm biochemical characteristics and fertilization rate remained globally unchanged whatever the station. Mortality and abnormality rates measured at both hatching and at the end of yolk sac resorption stages followed the same trend than the sperm DNA damage, demonstrating an impact of river water quality on nase fitness through a loss of sperm DNA integrity. Since the level of both abnormalities and mortality measured in offspring of fish caught in the most contaminated area reached high values up to 15 % and 80 % respectively, the hypothesis of an observed nase decline in Rhône River stemming through selection forces can be put forward.Possible modifications in habitat and food resources threatened by river regulation and climate change, and immunosuppression triggered by high level of chemical pollution should be kept into account for a valuable assessment of human activities consequences on aquatic ecosystem functioning.

Mechanistic links between molecular alterations and transgenerational effects of depleted uranium and radionuclides in Daphnia magna
F. Alonzo, D. Plaire, F. Parisot, C. Adam-Guillermin, IRSN; M. Trijau, IRSN/PRP-ENV/LECO / PRPENVSERISLECO; J. Garnier-Laplace, IRSN / PRPENVSERIS
Understanding how toxic contaminants affect species at sub-cellular, histological, physiological, organism, population levels of biological organization is a major research goal in both ecotoxicology and radioecology. Mechanistic links among the observed perturbations are necessary to predict consequences for survival, growth and reproduction which are critical for population dynamics. Time scales at which such links are studied are rarely relevant for natural biota. With a small size and short life cycle, the cladoceran crustacean *Daphnia magna* is suitable for studying contaminants effects over several generations. Multigenerational toxicity studies are much more relevant to natural biota for which exposure can involve many successive generations. Multigenerational studies of toxic effects were conducted under controlled conditions in *D. magna* exposed to depleted uranium (U), americium-241 (Am-241) and cesium-137 (Cs-137), representing respectively a dominantly chemotoxic metal, an alpha internal contamination and a gamma external radiation. Results showed in all cases that toxic effects on physiology and life history (survival, body size, fecundity) increased in severity across generations. These observations demonstrated that measured effects in one generation might not be representative of toxicity in the following offspring generations, and ultimately of the population response. Reduction in somatic growth and reproduction induced by depleted U were analyzed using a DEBtox approach (dynamic energy budget applied to toxicology). Modelling results suggested that depleted U primarily affects assimilation. This metabolic mode of action was confirmed by measurements of assimilation reduction and observations of histological alteration of the digestive epithelium. However the mechanisms involved in the transgenerational increase in sensitivity remained unknown. Recent studies investigating DNA damage in daphnids exposed to depleted U and Cs-137, demonstrated that molecular alterations were accumulated in females over the course of exposure and transmitted to their progeny. Such alterations were interpreted as the underlying mechanism causing the increase in effect severity over generations and will be investigated, as a future perspective, during exposure to Am-241. DEBtox models considering the accumulation and transmission of genetic damage were used to analyze toxic effects of depleted U, Cs-137 and Am-241 in daphnids exposed over successive generations.

404
Evolution of Lymnaea stagnalis inbreeding depression under pesticide chronic exposure
A. Duval, INRA Agrocampus Ouest; M. Collinet, M. Coke, INRA; M. Coutellec, INRA / Ecology and Ecosystem Health UMR INRA Agrocampus Ouest
Ecological and genetic factors may modulate the toxicity of chemicals to natural populations. In particular, inbred populations may be more sensitive to pollutants than their outbred conspecific counterparts, due to high homozygosity, loss of genetic diversity, or increased genetic load. On the other hand, strong inbreeding, such as expected in highly selfing hermaphrodites, may have a positive effect on population response to chronic (multigeneration) exposure to toxicants. First, selfing may facilitate the response to the selection exerted by a toxicant, through a transmission of coadapted gene complexes more efficient than under random mating. This is due to the fact that selfing reduces effective recombination. Furthermore, evolutionary theory predicts that spontaneous deleterious mutations can be preferentially purged under selfing, whereas they are maintained for a longer time within outcrossing populations, as masked in heterozygotes. Thus, high and longlasting inbreeding may have positive effects on fitness, and possibly on the ability to face chronic environmental stress. We tested these hypotheses in the freswhwater gastropod *Lymnaea stagnalis*, using a three-generation exposure to the pro-oxidant herbicide diquat. A total of 16 lineages derived from a highly diverse genetic pool were either exposed to diquat at early stages or maintained under control conditions. Chemical exposure was crossed with the mating system, i.e., in each treatment (control, diquat), four lineages were forced to self-fertilize and four other lineages were allowed to outcross. After three generations, inbreeding depression, the fitness decrease of selfed progeny relative to the outcrossed one, was compared across treatments. Inbreeding depression increased under diquat exposure, reflecting an aggravation of the toxic effects under inbreeding. In other words, selfing did not improve the response to selection by diquat. However, selfed lineages also showed an increase in trait variance, especially under diquat exposure. Some inbred lines performed better than some outcrossed lines, suggesting that the response to selection might depend on lineage genetic composition. In terms of toxicity testing, the use of strains maintained for generations in the laboratory may be questionable, due to high inbreeding and depleted genetic variability. To circumvent this drawback and improve ecological risk assessment, we recommend the use of at least two distinct original populations.

Endocrine Disruptors: Exposure, Hazard & Risk Assessment (II)

405
Thyroid disruption in zebrafish (Danio rerio) larvae: different molecular initiating events leading to impaired eye development and visual functions
L.A. Baumann, University of Bern / Centre for Fish an Wildlife Health; A. Ros, University of Bern / Centre for Fish and Wildlife Health; K. Rehberger, University of Bern / FiWi; S.C. Neuhauss, University of Zurich / Institute of Molecular Life Sciences; H. Segner, University of Bern / Centre for Fish and Wildlife Health
The vertebrate thyroid hormone system is important for multiple developmental processes, including eye development. Thus, its environmentally induced disruption may impact important fitness-related parameters like visual capacities and behaviour. The present study investigated the relation between initiating molecular events of thyroid disruption and morphological and physiological changes of eye development of zebrafish (*Danio rerio*). Two test compounds representing different molecular modes of thyroid disruption were used: propylthiouracil(PTU) as enzyme-inhibitor within thyroid hormone synthesis, and tetrabromobisphenol A (TBBPA) as ligand of thyroid hormone receptors. Both test chemicals significantly altered transcript levels of thyroid-related genes in a compound-specific way. Despite differing molecular response patterns, both treatments resulted in similar pathological alterations of the eyes such as reduced size and pigmentation, which were concentration-dependent. The morphological changes translated into impairment of swimming activity and visual performance of the larvae: the optokinetic response was significantly and concentration-dependently decreased in both treatments, together with a significant increase of light preference of PTU-treated larvae. This study provides first evidence that thyroid disrupting compounds do not only impair morphological but also functional eye development in fish early life stages, and that the phenotypic outcomes appear to be similar for different modes of molecular action of the thyroid disruptors.

406
Obesogenic effects in Daphnia magna. An emerging endocrine disrupting effect
C. Barata, CSIC / Environmental Chemistry; R. Jordão, CESAM & University of Aveiro / Biology; B. Campos, IDAEA-CSIC / Environmental Chemistry; F. Casas, CSICIQAC; E. Garreta, CSICIDAEA; M.F. Lemos, Instituto Politécnico

de Leiria / MARE IPLeiria; A.M. Soares, Universidade de Aveiro / Department of Biology and CESAM; R. Tauler, CSICIDAEA
Assessment of endocrine disrupters has been largely focused on vertebrates and on disruption of the hypothalamic-pituitary--gonadal/thyroidal axes of laboratory animals. There are, however, many compounds able to disrupt other nuclear receptor signaling pathways. An important group of endocrine disrupters are obesogens that disrupt the retinoic X receptor and PPAR and cause obesity in vertebrates. There is, however, little evidence of obesogenic effects in non vertebrates.. A recent study showed that tributyltin (TBT) activated the ecdysteroid, juvenile hormone and retinoic X receptor signaling pathways, and disrupted the dynamics of neutral lipids in the crustacean *Daphnia magna* impairing the transfer of triacylglycerols to eggs and hence promoting their accumulation into lipid droplets in post-spawning females. Tributyltin disruptive effects translated into a lower fitness for offspring and adults. The present study aims to addresses the disruptive effects of existing compounds alone and in mixtures on the lipid droplet dynamics in post-spawning females and their health effects.*D. magna* individualswere exposed 12 chemicals that included vertebrate obesogens (TBT, triphenyltin, bisphenol A (BPA), 4-nonylphenol (NP), di-2-ethylhexyl phthalate), other contaminants known to affect arthropods (pyriproxyfen (PP), fenarimol (FEN), methoprene (MET), emamectin benzoate (EM and fluoxetine (FX)), as well as the natural hormones methyl farnesoate (MF), 20-Hydroxyecdysone (20E). Reproductive effects were assessed by Life History analysis methods. Quantitative changes in storage lipids were studied using Nile red staining and ultra-performance liquid chromatography coupled to a time-of-flight mass spectrometry. Ten compounds disrupted storage lipid in a concentration related manner enhancing (TBT, MF, PP, BPA, 20E) or decreasing (NP, FEN, EM, MET, FX) their accumulation into lipid droplets in post-spawning females. Joint binary mixture effects indicated that the studied compounds acted on storage lipids additively and non-additively disruption the signaling pathways of ecdysone, methyl farnesoate and retinoic X receptors. In eight compounds disruptive effects translated into detrimental effects in growth and or reproduction.

Occurrence of alkylphenols, volatiles, and metals in tap water in households with epoxy coated water pipes

J. Rajasärkkä, Masaryk University / RECETOX Research Centre for Toxic Compounds in the Environment; M. Pernica, Masaryk University / Research centre for toxic compounds in the environment; J. Kuta, J. Lačňák, Masaryk University / RECETOX Research Centre for Toxic Compounds in the Environment; Z. Simek, Masaryk University / Research centre for toxic compounds in the environment; L. Blaha, Masaryk University, Faculty of Science / Research centre for toxic compounds in the environment RECETOX
Organic chemicals in tap water originate from several sources. Organic pipe materials are a potential source of contaminants. Compared to communal distribution system small water pipes in households have potentially greater impact on water due to higher surface-to-volume ratio [1]. Organic pipe materials include pipe inner surface lining materials such as epoxy resins. Epoxy lining has been used as a cost-effective alternative to renovate old water pipes. Most common component in epoxy resins is bisphenol A (BPA). Leaching of chemicals such as the endocrine disruptor BPA has been shown to occur from epoxy linings in pipes [2]. In addition, epoxy liners of food and beverage cans has been shown to leach BPA to the contents [3]. Consequently, long-term durability and safety of drinking water pipe epoxy linings has been a topic of discussion. In this study drinking water from apartment houses with different age epoxy linings were studied. Samples were collected in summer 2015 from 6 houses with epoxy lined drinking water pipes and a drinking water treatment plant (DWTP) in Helsinki, Finland. Tap samples were collected after about 8 hours of discontinued water usage and after 2 min flowing, both on cold and hot lines. For comparison further sampling were done in December 2015 at 5 other sites with different age and material pipes. Samples were analyzed for alkylphenols BPA, bisphenol F (BPF), 4-t-octylphenol (OP), and 4-n-nonylphenol (NP) with HPLC-MS [4], and for volatile organic compounds, and metals (IPC-MS). Total (anti)estrogenic and (anti)androgenic potency and BPA-like activity will also be tested with yeast-cell-based assays [5, 6]. Bisphenol A was frequently detected in water of houses with epoxy lined pipes. DWTP samples had no detectable BPA. Incoming water and cold flowed water had less than 16 ng/L of BPA, while pipe-incubated cold water had concentrations up to 33 ng/L. Hot water had clearly higher levels of BPA in two sites, even up to 1,65 µg/L, whereas in three sites BPA levels were below 60 ng/L. BPF, NP, and OP were detected only in few samples below 2; 1,4; and 22 ng/L, respectively. BPA in tap water samples mainly originates from the epoxy lining, but the levels are low in cold water. In hot water BPA levels were relatively high in 2 houses which were also the oldest studied renovation sites. Possible during time epoxy lining is becoming eroded especially at the hot water line, causing elevated BPA concentrations.

408

A novel fractionation approach using four columns in parallel for effect-directed analysis of antiandrogenic compounds in a river water extract

M. Muschket, UFZ- Helmholtz Centre for Environmental Research / EffectDirected Analysis; C. Di Paolo, RWTH Aachen University / Ecosystem Analysis ESA; M. Krauss, Helmholtz centre for environmental research - UFZ / Effect Directed Analysis; K. Kaufmann, RWTH Aachen University; H. Hollert, RWTH Aachen University / Department of Ecosystem Analysis; W. Brack, Helmholtz Centre for Environmental Research UFZ / EffectDirected Analysis
Within the past decade a number of studies correlated reproductive disorders in humans and wildlife with endocrine disrupting compounds. The focus of research was on chemicals acting as anti-/estrogens. Moreover, there is an increasing evidence for the impact of antiandrogens on this kind of disorder such as the occurrence of feminized fish in river water that has been associated not only with estrogenic but also antiandrogenic compounds. Thus, the aim of this study is the identification of so far unknown antiandrogens by effect-directed analysis (EDA) in the extract of a small, wastewater-impacted river in Germany. The success of EDA is essentially influenced by the fractionation procedure. This study introduces a novel fractionation approach using four orthogonal columns in parallel as a time-efficient alternative to the classical, sequential fractionation scheme. Chemical and toxicological analysis is performed on fractions from the different separation systems. The candidate peaks common in bioactive fractions are selected and subjected to toxicant identification. For the selection of suitable LC stationary phases 52 known or suspected androgens and anti-androgens were separated on 17 different stationary reversed-phases owning widely differing chemistries. The retention data were analyzed using several procedures including principal component analysis, spearman rank correlation of the retention time plots and the approaches according to Gilar et al. and Camenzuli. An aminopropyl-, octadecyl-, pyrenyl ethyl and additionally according to the promising results in the literature a pentafluorophenyl phase were selected. The antiandrogenic activity of the fractions was analyzed using a miniaturized anti-AR CALUX assay due to the limited sample amount at a non-cytotoxic concentration range. One single active fraction was observed for each fractionation with the four selected columns. Non-target screening of the active fractions by use of high resolution mass spectrometry is currently being performed.

Determination of eleven thyroid hormones and metabolites in plasma and tissue: description of analytical method and ecotoxicological case studies

M. Hansen, University of California, Berkeley / Civil Environmental Engineering Integrative Biology; X. Luong, University of California Berkeley / Department of Integrative Biology; D.L. Sedlak, University of California Berkeley / Civil Environmental Engineering; T. Hayes, UC Berkeley / Integrative Biology
Thyroid hormones, such as thyroxine (T_4) and 3,3',5-triiodothyronine (T_3), are vital in numerous physiological processes (e.g. embryonic development, metabolism, cell differentiation and proliferation, cognitive development, and thermogenesis). However, little is known regarding how thyroid hormones affect stress regulation and behavior. Many factors control circulating levels of the bioactive hormone (T_3), consequently not only T_4 and T_3 measurements are vital, but also so-called inactive thyroid hormone metabolites are necessary for a comprehensive description of homeostasis. Circulating thyroid hormones in plasma are typically in low ppt-levels, and can be used as a diagnostic tool during e.g. pregnancy, or for hypothyroidism, hyperthyroidism and endocrine disruption diagnosis. A prerequisite for investigating thyroid hormone disrupting effects is a need for establishing highly sensitive analytical methods. In the present work, we describe an isotopic-dilution LC-MS/MS methodology to determine eleven thyroid hormones and metabolites in 'pico-gram' levels in plasma and tissue from wildlife. The protein-unbound fraction of hormones is largely recognized as the circulating 'bioavailable' fraction. Consequently, free and total thyroid hormone concentrations in blood and plasma are reflected. Finally, we apply the developed methodology to investigate thyroid hormone levels in individual tadpoles (*Xenopus laevis*) ranging from NF stages 55-61 and in plasma from adult *X. laevis*, both from controlled in-vivo studies, and in wildlife samples (e.g. whale, fish, and amphibian).

Enantiospecific disruption of human steroidogenesis in vitro by the azole fungicide imazalil

A. Kretschmann, C.H. Hansen, University of Copenhagen / Section of Analytical Biosciences Department of Pharmacy; M. Escolà Casas, Aarhus University / Department of Environmental Sciences; L. Andernach, Johannes Gutenberg-Universität Mainz / Institute or Organic Chemistry; T. Opatz, Johannes Gutenberg-Universität Mainz / Institute for Organic Chemistry; K. Bester, Aarhus University / Department of Environmental Science; B. Styrishave, University of Copenhagen / Section of Analytical Biosciences Department of Pharmacy
Increasing evidence exists that several pesticides are likely to disrupt hormone homeostasis in humans and may contribute to endocrine related diseases like infertility, obesity and different types of cancers. However, although many pesticides are chiral, hardly any studies exist elucidating how the endocrine disrupting (ED) potential depends on the enantiomeric form. This information is needed for a more precise risk assessment of chiral pesticides and for the development of safer pesticides by for example eliminating the toxic enantiomer

from the pesticide formulation. An important target of various ED chemicals is steroidogenesis, i.e., the synthesis of steroids such as progestogens, sex steroids (androgens and estrogens), and corticosteroids, which control the complex physiological processes associated with growth, reproduction, and pregnancy. A group of pesticides shown to disrupt steroidogenesis are azole fungicides. In this project we analyzed *in vitro* the disruption of human steroidogenesis by the chiral azole fungicide imazalil in dependence of the enantiomeric form. As model system we used the human adrenocortical carcinoma cell line H295R, which expresses all important human steroids. Pure enantiomers of imazalil were isolated with enantioselective HPLC and the absolute configuration of the enantiomers was identified with circular dichroism. H295R cells were exposed for 48 h to racemic imazalil as well as to the individual enantiomers in concentrations ranging from 0.001 – 8 μM. After exposure 17 steroids were quantified in the cell medium using HPLC-MSMS. Racemic imazalil inhibited the synthesis of several steroids belonging to androgens, estrogens and corticosteroids with EC50s in the range of 0.018 – 1.1 μM. First results show that imazalil enantiomers differ in their disruption of some steroidogenic pathways: *S*-imazalil inhibited estrone production approx. 7 times stronger than *R*-imazalil, whereas progesterone production was stimulated by *R*-imazalil to a 3 times higher extent than by *S*-imazalil. These results indicate that the disruption of steroidogenesis by azole fungicides is enantiospecific *in vitro*. Which significance our findings have for the risk of endocrine related diseases has to be tested in future *in vivo* studies.

Science based strategies for the environmental assessment and management of pharmaceuticals and veterinary medicines

411

Industry Approach to Managing Potential Risks from Active Pharmaceutical Ingredients in Manufacturing Effluent

F. Mastrocco, Pfizer, Inc. / Department of Environment Health Safety; K. Kappler, Johnson & Johnson / Environmental Engineer; D.J. Caldwell, Johnson & Johnson

To address stakeholder concerns with pharmaceuticals in the environment (PiE), the pharmaceutical industry has developed a proactive product stewardship approach entitled, ‘Eco-Pharmaco-Stewardship’ (EPS) consisting of three ‘pillars’, namely; enhanced environmental risk assessment (eERA), extension of the scientific knowledge base (IMI-iPiE), and manufacturing effluent management, the focus of this presentation. Through the application of a risk-based approach, the industry is seeking to ensure that manufacturing effluent discharge is effectively managed to minimize environmental risk across the supply chain. The development and application of step-by-step guidance by several manufacturers will be described, as well as, steps taken to ensure all in the supply chain are aware of practices that can be deployed to ensure that risks from manufacturing effluent are low. The use of a maturity ladder concept to establish current program sophistication level and gauge advancement will also be presented.

412

The need for targeted testing to improve the regulatory environmental risk assessment of veterinary medicines used in aquaculture

A. Lillicrap, A. Macken, NIVA / Ecotoxicology and Risk Assessment; K.V. Thomas, NIVA Norwegian Institute for Water Research / Product Metabolism

The use of pesticides to treat farmed salmonids for infestations of salmon lice has increased significantly over the recent years. Controlling salmon lice infestations is not simply an economic goal, but also it is a requirement that fish farms maintain levels below 0.1 lice per fish to limit transmision to wild poulations of salmonids. With the emergence of more resistant strains of salmon lice, control strategies are becoming more aggressive and the consequence to non-target organisms is currently receiving a great deal of media publicity. For some pesticides used to treat salmonids, standard acute toxicity tests may be sufficient to predict environmental effects on non-target organisms exposed to veterinary medicines in aquaculture. However, standard acute toxicity tests are not sufficiently protective to estimate possible environmental effects of substances that have a very specific mode of action, for example chitin synthesis inhibitors. Therefore, more targeted assessment strategies using non-standardised test methods aimed at the specific mode of action is necessary to capture the possible long term effects of these pesticides. This presentation describes some of the pesticides that are currently being used to treat salmon lice and the possible environmental impact that they may be having on non-target organisms plus recommendations for improvements to the environmental risk assessments (ERA) of veterinary medicines used in aquaculture.

413

Refined exposure estimation to support an Environmental Assessment for a veterinary medicine

C.M. Holmes, I. Khanijo, Waterborne Environmental, Inc.; J. Amos, Waterborne Environmental, Incorporated / GIS Specialist; A. Ritter, Waterborne Environmental, Inc.; H. Zahner, US FDA / Center for Veterinary Medicine; E.M. Silberhorn, US Food & Drug Administration / Center for Veterinary Medicine; D. Merritt, Zoetis

The U.S. Food and Drug Administration, Center for Veterinary Medicine, evaluates whether significant environmental impacts would occur with the approval of new animal drugs pursuant to the National Environmental Policy Act. The approval process may require the preparation of an environmental assessment (EA), which contains sections addressing problem formulation, environmental fate, exposure, effects and risk characterization. Using a recent EA as a framework, this presentation will focus on the refinement of environmental exposure estimates using spatial techniques to identify representative and protective environmental scenarios, and link them to exposure models commonly used in the U.S. Environmental Protection Agency (USEPA) pesticide registration process. A Geographic Information System (GIS) was used to identify regions of high exposure potential across the US based on beef cattle characteristics and climatic conditions. From within each region, a single vulnerable watershed was selected and characterized for watershed-scale modelling following USEPA Tier-2 pesticide exposure approaches. Three potential sources of chemical were modelled: feedlots, agricultural fields applied with manure collected from the feedlots, and pasture. Using PRZM and EXAMS models, runoff and erosion inputs to surface water from these sources were assessed over a 30-year timeframe to produce final PECs suitable for use in the effects portion of the EA. The results of the national vulnerability assessment identified five regions with diverse intensive-use characteristics. From within these, a single intense-use watershed was selected and modelled. Loadings from each of the land covers were combined on a daily basis and transported to the receiving water body, from which daily PECs were calculated. Based on the aggregate aquatic exposure, no significant effects were identified and a Finding of No Significant Impact (FONSI) was determined. The process presented here discusses the development of refined methods to estimate exposure using spatial techniques to identify representative and protective environmental scenarios. It linked these scenarios to accepted EPA exposure models which addressed all potential sources of chemical loading and produced a series of surface water PECs suitable for risk characterization. This approach is a robust and viable methodology incorporating real world information but maintains inherent safety assumptions from USEPA Tier-2 pesticide framework.

414

Use of Acute and Chronic Ecotoxicity Data in Environmental Risk Assessment of Pharmaceuticals

J. Vestel, Merck & Co., Inc.; D.J. Caldwell, Johnson & Johnson; L.A. Constantine, Pfizer, Inc. / Pharmacokinetics Dynamics and Metabolism; V. D'Aco, Quantum Management Group, Inc.; T. Davidson, Bristol-Myers Squibb / EHS; D.G. Dolan; S. Millard, Probability Statistics and Information; R. Murray-Smith, Richard Murray-Smith; N. Parke, Eli Lilly and Company / Global HSE Environmental Affairs; J. Ryan, GlaxoSmithKline; J. Straub, F.Hoffmann-La Roche Ltd / Roche Group Safety Health Environmental Protection; P.W. Wilson, Sanofi U.S., Inc. / Health Safety and Environment

For many older pharmaceuticals, chronic aquatic toxicity data are limited. To assess risk during development, scale-up and manufacturing processes, acute data and physicochemical properties need to be leveraged to reduce potential long-term impacts to the environment. Aquatic toxicity data were pooled from daphnid, fish and algae studies for 102 active pharmaceutical ingredients (APIs) to evaluate the relationship between predicted no-effect concentrations (PNECs) derived from acute and chronic tests. The relationships between acute and chronic aquatic toxicity and the *n*-octanol/water distribution coefficient were also characterized. Statistically significant but weak correlations were observed between toxicity and log Dow, indicating Dow is not the only contributor to toxicity. Both acute and chronic PNEC values could be calculated for 60 of the 102 APIs. For most compounds, PNECs derived from acute data were lower than PNECs derived from chronic data, with the exception of steroid estrogens. 7% of the PNECs derived from acute data were below the EU action limit of 0.01 μg/L and all were anti-infectives affecting algal species. 8% of available PNECs derived from chronic data were below the EU action limit and fish were the most sensitive species for all but one API. These analyses suggest that the use of acute data may be acceptable if chronic data are unavailable, unless specific mode of action concerns suggest otherwise.

Evaluating the Risk of Pharmaceuticals in the Terrestrial Food Web

L. Carter, University of York / Environment Department; T.G. Bean, University of Maryland / Department of Environmental Science and Technology; A. Boxall, University of York / Environment Department

This study investigated the risk to bird species consuming earthworms contaminated with active pharmaceutical ingredients (APIs) using a combination of previously published earthworm bioconcentration factors (BCFs) and new experimental results. Food chain transfer scenarios were subsequently compared between soil - earthworm - bird using a range of pharmaceuticals. In total, an exposure assessment was carried out to evaluate food web transfer of selected APIs (carbamazepine, diclofenac, fluoxetine and orlistat) through 28 different field scenarios, taking into account the effect of soil type and species traits on earthworm API uptake. API residues were predicted in two earthworm species, namely *Eisenia fetida* and *Lumbricus terrestris* from experimentally determined BCFs and environmentally relevant soil concentrations. Using a combination of calculated API residues in earthworms together with known consumption data of earthworms for the selected bird species, the daily intake of each API by song thrush, rook, starling, lapwing and common gull was modelled. Based on these exposure scenarios the resulting earthworm concentrations reached a maximum of 2462.03 μg/g. Subsequent analysis demonstrated that the food web transfer of selected pharmaceuticals reached a maximum daily intake of 459.8 μg per bird. Ultimately, a range of parameters can influence the bioavailable fraction of the API in the soil which can lead to a range of bird daily intake values. Sandy soils typically have higher bioavailability than clay soils which can influence earthworm API uptake and thus bird exposure. In general, the larger BCFs for *L. terrestris* resulted in a higher uptake in comparison to *E. fetida*, given a fixed soil concentration, and thus a greater intake by the bird species on a per g basis. To evaluate any potential long term toxicity by birds ingesting API contaminated earthworms the bird elimination half-life required to accumulate the human therapeutic dose (HTD) in 90 days was subsequently calculated. The bird species included in this analysis would require elimination half-lives in the range of 1 to 3 orders of magnitude longer than humans to accumulate the HTD. Therefore, as birds typically have faster metabolic rates than humans, and so are likely to eliminate APIs quicker than humans it is unlikely that the calculated elimination half-lives required to accumulate the HTD would be observed.

416
Post-approval environmental management of human medicinal products: An extended environmental risk assessment (eERA) framework
J. Snape, AstraZeneca UK Ltd. / AstraZeneca Global Environment; J. Ericson, Pfizer Inc. / Environmental Sciences PDM; T. Davidson, Bristol-Myers Squibb / EHS; R.D. Meyerhoff, Eli Lilly and Company / Lrl Health Safety And Environmental; J. Ryan, GlaxoSmithKline / Corporate Environment Health Safety Sustainability; R. Laenge, Bayer Pharma AG / Dept Experimental Toxicology; J. Straub, F.Hoffmann-La Roche Ltd / Roche Group Safety Health Environmental Protection; R. Journel, SANOFI; S. Eskola, Efpia; K. Nedog, EGA; M. Moussa, AESGP
The Association of European Self-Medication Industry (AESGP), European Federation of Pharmaceutical Industry Associations (Efpia) and the European Generics Association (EGA) are currently looking to implement a holistic approach to the environmental management of human medicines products called EcoPharmacoStewardship (EPS). Within this EPS initiative, AESGP, Efpia and EGA propose to extend the ERA paradigm into the post-approval phase (specifically for new APIs) to refine usage figures based on total substance use and investigate and report environmental concerns identified post-approval. Should the ERA outcome change as a result of these eERA activities, risk management options could be discussed with stakeholders and appropriate measures may be agreed by participants. Through three distinct phases, there are several benefits that eERA brings to the environmental assessment of human medicinal products containing new APIs. These include: (i) formalising post-launch commitments for addressing environment risk without impacting patient access to medicines, (ii) a risk assessment based on the total PEC arising from all products containing the same API, (iii) on-going assessment of the relevance and reliability of research findings, (iv) updating the ERA where necessary, (v) agreeing with regulatory agencies what follow up risk refinement and risk management measures that may be required, and (vi) determining the likelihood that any research findings can translate to an adverse impact in the wild. eERA offers a possible mechanism where industry can agree with the EMA and other stakeholders (including national competent authorities (NCAs)) on proportionate risk management measures where any significant environmental risks identified post-patient use would trigger appropriate further work to refine the ERA. Conversely, where post-authorisation surveillance does not indicate any significant risk for an API then no further action is needed until the next scheduled review of the ERA based on Total PEC. This presentation will describe the eERA process, its benefits, and discuss some of the challenges posed in its implementation.

Advancements in life cycle impact assessment method development (II)

417
Assessment of the impact of pesticide application in agricultural LCA: sensitivity analysis of PestLCI and USEtox
T. Waldvogel, Agroscope / Institute of Sustainability Sciences; A. Roesch, Agroscope Reckenholz-Tänikon Research Station ART / Agroscope; O. Daniel, E. Kohlschmid, Agroscope / Institute for Plant Production Sciences IPS; T. Nemecek, Agroscope / Institute for Sustainability Sciences ISS
The assessment of fate and ecotoxicity of pesticides within a Life Cycle Assessment (LCA) is a challenging task. On one hand the number and possible ecotoxic effects of the different active ingredients is high. On the other hand modelling the fate of a chemical substances in the environment is not straightforward regarding the complex interdependencies of the various processes. Current modelling of the fate of pesticides after their application in the Life Cycle Inventory (LCI) and the subsequent Life Cycle Impact Assessment (LCIA) in LCA studies and databases proved to be insufficient, since the fate of pesticides was not modelled in the inventory phase. In this analysis we scrutinized the two following models with improved bio-physical modelling: PestLCI and USEtox. PestLCI tackles the fate modelling of pesticides immediately after application, while USEtox provides characterisation factors (CF) assessing the impact of a pesticide in different environmental compartments. These two methods have been increasingly used in combination in recent LCA studies of agricultural production systems. In order to assess the practicability of PestLCI and USEtox for the calculation of agricultural LCA and to guide data collection we conducted a sensitivity analysis. The goal was to a) identify important input parameters, b) draw conclusions for the required precision of the input data, and c) to estimate where default values could be used. In the sensitivity analysis nine input parameters were independently varied according to prevailing conditions in Swiss agricultural practices. In line with previous sensitivity analyses performed with PestLCI, we found that soil and climate are critical parameters. In addition we found that the development stage of the crop, tillage, buffer zones, and drainage are further important input parameters. Low sensitivity of results was found for the input parameters irrigation, tillage, and share of macropores. Similar results were found in an additional sensitivity study where the impact score (IS) consisting of results from PestLCI and USEtox was assessed. The presented results suggest that further research is needed to define the soil and climate profiles that are requiered to cover the main agricultural areas. On the other hand we identified input parameters with low sensitivity where default values can be used. These findings help to structure and simplify the data acquisition and calculation of the impact of pesticides within a LCA.

Synergies and divergence between LCA human toxicity assessment and Risk Assessment approaches
M. CORNELUS; R.K. Rosenbaum, National Research Institute of Science and Technology for Environment and Agriculture - Irstea / UMR ITAP; S. Causse, EVEA; V. Grammont, A. Toise, INERIS; J. Garcia, P. OSSET, SCORE LCA
1. Introduction Beyond the assessment of toxic effects and risks within the framework of European regulations, such as REACh and CLP, other assessment methods for sanitary risks exist but differ from one country to another. Methodologies are different but always based on the founding principles of dose-response relationships and exposure scenarios describing the source-to-target vector. The complementarity of Life Cycle Assessment (LCA) and Chemical Risk Assessment (RA) may yield a more accurate and exhaustive approach to assess human toxicity. 2. Materials and methods 2.1. Panorama of methods assessing human toxicity Various approaches to assess human toxicity risks exist and allow to supply toxicity data. The classifications, such as those established by the European Union, allow to identify hazards of substances. Risk and hazard based approaches typically apply (reasonable) worst-case assumptions for modelling and data selection. In contrast, LCA toxicity assessment methods apply the concept of best-estimates. Another important difference is that RA is site-specific whereas LCA is site-generic. A number of relevant methods for human toxicity assessment within the LCA and RA frameworks have been analysed in order to allow for a mapping of the methods. The results and the divergences identified between the methods are presented in a condensed way. 2.2. Complementarities The methods have been analysed according to many criteria. This talk will underline the similarities and differences as well as the advantages and the associated drawbacks linked to each method. To support this analysis, a comparison based on a case study applying both LCA and RA methods was performed for the human toxicity assessment of a paraben-free cosmetic formula. A detergent was also analysed with different methods. Throughout the study, independent scientific experts have been associated to assure a peer-review of this study. 3. Results and discussion Propositions for the correct interpretation of results as well as their limitations and research needs were identified. Methodological issues will be discussed. Moreover, guidelines and recommendations for human toxicity assessment will be proposed, detailing which method serves which purpose, where they overlap and where they complement one another. This study invites experts to work together to find solutions to the current issues in human toxicity assessment.

Addressing fresh water ecotoxicity impact category under the EU Product Environmental Footprint (PEF)
E. Saouter, EU Commission JRC / Sustainable Assessment UNit; M. Secchi, University of Milano Bicocca, / Department of environmental and earth science; S. Sala, European Commission - Joint Research Centre / Sustainability Assessment unit; R. Pant, European Commission / Institute for Environment and Sustainability; K. Aschberger, European Commission Joint Research Centre / Institute for Health and Consumer Protection IHCP; S. Bopp, European Commission - Joint Research Centre / Systems Toxicology Unit
The UNEP-SETAC Life Cycle Initiative recommended LCA method to assess the impact of chemicals on the aquatic environment and human is the USEtox model.

USEtox is also the EU Commission recommended method to calculate 'Ecotoxicity for fresh water' and 'Human toxicity' impact categories in the context of the EU Commission Product Environmental Footprint (PEF). This model is now considered by the LCA community as the most consensual for estimating the impact of chemical emissions of human health and aquatic ecosystems. Since its release, USEtox has been widely used by research organizations and consulting firms, but only very recently, in the context of the PEF, this model has been systematically used and evaluated by several sectors of industries for the purpose of product comparison and communication. This 'real life testing phase' has revealed some issues that required immediate attention if the result of this model is to be used for hot spot analysis, product improvement, product comparison and communication. In January 15th 2015, the EU Commission has organized a workshop with all the PEF pilots that have used the USEtox model in their screening studies. The main conclusions from this meeting were: The experience of using the USEtox model by all pilot members was somehow disappointing. The model was not criticized as such, but rather the outcomes of the calculation (i.e characterisation factors (CFs)). The lack of transparency as well as complexity of using the model to calculate new characterisation factors were identified as a limitation for further use. The data (physico-chemical, half-life and toxicity) that have been used to calculate the CFs provided with the model (about 3000) seems to be a source of significant differences, controversies and criticisms. For many substances, especially fate and effect data may not be suitable as currently used in USEtox. Most PEF Pilots recommended not to use the model further before agreement is reached on the selection of input data After this workshop, the Joint Research Centre (JRC-Ispra) has conducted an in-depth evaluation of the model and data used to calculate CFs. This paper aims at highlighting the main areas where modifications could be made to improve the reliability and acceptance of the CFs

420
Analysis of the different technique to include noise damage in life cycle assessment. A case study for car tires.
R. Meyer, LIST / Environmental Research and Innovation; E. Igos, E. Benetto, Luxembourg Institute of Science and Technology (LIST) / Environmental Research and Innovation
WHO (2011) reported very comprehensively on the burden of disease from environmental noise, highlighting noise as a threat to public health problem. Despite this need, the integration of traffic noise damages on human health in life cycle assessment (LCA) is still debated. Although several methodological attempts were advanced to fill in this gap, none of them has become consensual so far. The objective of this study is threefold: i) to analyse how the different methods for noise damage assessment are sensitive to different input noise levels; ii) to compare the results obtained from the three methods and iii) to evaluate the importance of noise damages on human health as compared to other burdens contributing to the DALYs. To this aim, three methods for noise damage assessment are investigated. A case study on car tires is considered as seminal example of functional unit to highlight and discuss the differences between the results obtained from the three methods. For our case study, three different tires are considered: one reference tire, and two tires (Tire 1 and Tire 2) with improved acoustical characteristics provided by a tire manufacturer. The complete LCA of the car tires (functional unit: a tire used over one kilometre) was also conducted using the ReCiPe method following the hierarchist perspective and average weighting set (H,A). i)The results show that all the noise characterization methods are sensitive to the differences in the acoustical characterises of the tires. Thus they allow reflecting in a quantitative way the improved sound level performance of the tire into clear impact differentials expressed in DALYs. ii) The dispersion of the results obtained from the methods show the need for further refinement of the assessment methodology to improve the accuracy and consistency of the integration of noise impact in LCA. iii) Despite the variation between the methods used, noise impact represents at least 90% of the total impact of the tires on human health. It highlights the importance of taking into account noise impact in LCA.

421
The development of an operational LCIA-methodology with impact categories based on the control variables in the Planetary Boundaries framework
M. Ryberg, Technical University of Denmark / Quantitative Sustainability Assessment Department of Management Engineering; M. Owsianiak; M. Hauschild, DTU Management Engineering / DTU Management Engineering
This study presents a first attempt at an operational LCIA-methodology basing the definition of the impact categories on the control variables as defined in the Planetary Boundaries (PB) framework. The PB-framework introduced a set of biophysical Earth system processes and defined quantitative PBs that have to be respected for Earth to remain in the Holocene state. The concept is attracting a strong interest from industry as companies seek to assess and communicate the environmental performance of their products relative to the PBs. The PB-framework has previously been attempted included in LCA as part of normalization and weighting. The limitations of both attempts are the lack of spatial differentiation for spatially differentiated PBs and the requirement for harmonizing the control variables with indicators already used in life-cycle impact assessment (LCIA). A way to overcome these limitations is to directly use the control variables in the PB-framework as impact categories in LCIA, which is also the objective of this study. This work defines a mathematical framework for a LCIA-methodology where Characterization Factors (CFs) are included for all Earth system processes in the PB-framework, for all substances contributing to effects on the Earth system processes and expressed in the units of the control variables. Except for novel entities and biosphere integrity which are currently excluded from the LCIA-methodology because the former is lacking a planetary boundary metric while a full understanding of the cause-effect chain is missing for the latter. The CFs were estimated by identifying the environmental models needed to model the control variables of the PB-framework and adapting these to fit the LCIA-framework. This work provides a full set of CFs for all the Earth system processes in the PB-framework. The new LCIA-methodology provide additional and complementary insights which cannot be achieved with traditional LCIA-methodologies. The results provide information on the environmental impacts of the assessed products and solves previous problems with approximative links between control variables in the PB-framework and current LCIA impact categories. The new insights can be used for communicating the product's environmental performance and to support definitions of absolute reduction targets relative to the PBs.

Passive sampling of organic micropollutants and toxicity assessment: opportunities, challenges and innovations (II)

422
Passive sampling and toxicity profiling: a case study in Rivers Meuse and Rhine, The Netherlands
T. Hamers, VU University Amsterdam, Institute for Environmental Studies (IVM) / Institute for Environmental Studies; F. Smedes, Masaryk University / RECETOX   Research centre for toxic compounds in the environment; J. de Weert, DELTARES; E. Van den Brandhof, National Institute for Public Health and the Environment RIVM; D. van de Meent, RIVM / DMG; D. DeZwart, DdZ-Ecotox
The TIPTOP project hypothesizes that time-integrative passive sampling followed by toxicity profiling is a toxicologically and ecologically more relevant and more protective approach for chemical water quality assessment than the assessment based on a comparison between concentrations of predefined individual compounds to their Environmental Quality Standard (EQS). To test this hypothesis, a demonstration study was designed at well-defined WFD sampling sites in the Dutch delta. Time-integrative sampling was performed using partitioning-based and adsorption-based passive samplers. Toxicity profiling was performed using a test battery consisting of in vitro and in vivo bioassays. Currently, all chemistry and toxicity profiles are available. Several approaches are followed to interpret these profiles in a toxicological and ecological context. First of all, the chemical data are used to make a traditional comparison between water concentrations of individual contaminants and their environmental quality standard concentration defined within the WFD. Moreover, the chemical analyses are used to determine the contribution of the analyzed compounds to the observed toxicity and to calculate the potentially affected fraction of species by exposure to these multiple substances (msPAF). Moreover, molar concentrations in the passive samplers are used to estimate to what extent the critical bodyburden for narcotic compounds is reached and to estimate the msPAF for narcotics. Bioassay results are used to benchmark toxicity profiles from river sampling locations to WWTP effluents. In vitro bioassay results are further used to compare to newly derived trigger values, i.e. bioassay responses below which no ecological risk is to be expected. In vivo bioassay results for organisms belonging to six different taxonomic classes are used to derive a species sensitivity distribution (SSD) for each sampling location, which can be used to determine a msPAF value based on bioassay responses measured after exposure to the whole sample, rather than on a limited set of chemical data. Finally, calculated and measured msPAF values are compared to the actual biological monitoring data obtained at the very same sampling locations. The outcome of TIPTOP should ultimately lead to a proposal for a cost-effective approach for chemical water quality assessment.

423
Investigating the time-integrative properties of passive sampling for chemical monitoring and application in bioassays
F. Smedes, j. de weert, DELTARES; T. Hamers, Institute for Environmental Studies   IVM VU University Amsterdam; E. Van den Brandhof, National Institute for Public Health and the Environment RIVM
Regular chemical water quality assessment of surface water is performed by single grab sampling of the water and comparison to Environmental Quality Standard (EQS). A disadvantage is that a grab sample gives only a snap shot of the water quality and may not be representative for compounds with an irregular emission pattern. Application of (time-integrative) passive sampling might be a better strategy, because water is sampled over a longer period and a higher water volume can be sampled. After deployment of the samplers and extraction in the laboratory, these extracts can be used for chemical analysis in the same way as in

the regular monitoring and/or used in bioassays to perform toxicity profiling. Uptake of passive samplers depend on deployment time and water turbulence or flow. The time-integrative properties of sampling was investigated within the TIPTOP project for partitioning-based and adsorption-based passive samplers Silicone-rubber (SR) samplers and adsorption based Speedisk (SD) samplers were deployed in the water for short and long periods overlapping with each other. \n After deployment the samplers were extracted and analysed on targeted chemical analysis with LC-MS and GC-MS, including PAHs and a range of plant protection substances. In addition all extracts were subjected to toxicity profiling The release of Performance Reference Compounds dosed prior to deployment was used to estimate the sampling rate for Silicon rubber samplers which information was also used to estimate the water volume sampled by the speedisk. In the presentation the time integrative properties of the samplers is evaluated as well as the evolution of the results from toxicity profiling.

424
In silico prediction of sampling rates for polar organic chemical integrative samplers (POCIS)
L. Barron, Kings College London / Analytical and Environmental Science; T.H. Miller, Kings College London / Analytical and Environmental Sciences; J.A. Baz-Lomba, Norwegian Institute for Water Research (NIVA); C. Harman, NIVA / Environmental Contaminants; M. Reid, NIVA; S. Owen, AstraZeneca / Safety Health Environment; N. Bury, Kings College London / Division of Diabetes and Nutritional Sciences; K.V. Thomas, NIVA Norwegian Institute for Water Research / Product Metabolism
The modelling and prediction of polar organic chemical integrative sampler sampling rates (R_s) for 73 compounds using artificial neural networks is presented for the first time. Molecular descriptors were chosen based on previous retention descriptor models and also a genetic algorithm which shortlisted 24 descriptors from a total of 201 that covered topological, geometrical and physicochemical properties. Each network was validated by testing the predictive ability for an external validation dataset ($n = 6$) of benzodiazepines with the best network based on chromatographic retention molecular descriptors. The genetic selected descriptor network showed an average absolute predictive error of 0.0437 ± 0.02 L d^{-1} which contrasted to the retention descriptor network error of 0.0145 ± 0.008 L d^{-1}. The sum squared errors for the training, verification and test subset were 0.092, 0.062 and 0.121, respectively. The average predicted error for the verification ($n = 11$) and test ($n = 11$) set was 0.03 ±0.02 L d^{-1} of the experimentally determined R_s value. The network was built in triplicate to assess the variability of predictions across networks and in comparison to experimental variance which gave better or similar variance to the measured values. These novel findings indicate the potential of *in silico* predictive tools for R_s determination which represents significantly more economical approach than laborious laboratory based calibrations.

425
Performances of the Continuous Flow Integrative Sampler (CFIS) for monitoring organic pollutants in surface waters
A. Assoumani, R. Pedraza Berenguer, L. San Juan Tortasa, R. Tortajada Santonja, M. Gomez Lopez, LABAQUA SA; D. Carcajona, T. Atack, Ardtoe Marine Laboratory; J. LLORCA, Labaqua / CHROMATOGRAPHY
Passive sampling has recently emerged as an efficient alternative to conventional active sampling for monitoring organic pollutants in water. The technique consists in exposing the passive sampler in the water for days to weeks, depending on the sampler, to accumulate the target pollutants. Average concentrations integrated on the exposure period are then determined from the mass of pollutants sequestered in the sampler. The concentration of the target pollutants in the receiving phase allows reaching lower quantification limits than conventional sampling techniques. Moreover, this technique reduces dramatically analytical costs, as it provides realistic average concentrations with a single analysis. A passive sampler is typically composed of a receiving phase and a membrane that separates the receiving phase from the medium. Several passive samplers have been developed for targeting pollutants of different physical chemical properties, and especially different polarities. The Semipermeable Membrane Device (SPMD) has been developed for non-polar organic pollutants such as polychlorobiphenyls (PCB) and polycyclic aromatic hydrocarbons (PAH) in water whereas the Polar Organic Chemical Integrative Sampler (POCIS) targets polar organic pollutants such as pharmaceuticals and polar pesticides. However, depending on the target pollutants, the performances of these passive samplers may depend on the exposure conditions, and especially on flow velocity. We have recently developed an automated, fully submersible, integrative sampling device to monitor both non-polar and polar organic pollutants in different types of water, the continuous flow integrative sampler (CFIS). Unlike other devices, the performances of the CFIS are independent from flow velocity. The performances of the CFIS were assessed and compared with those of spot sampling for monitoring hormones, pharmaceuticals, PCB, PAH, hydrophobic pesticides and plasticizers in the inflow and the outflow waters of a fish farm in Ardtoe (Scotland). Exposure campaigns of 10 days have been started in July 2015, for one year. For each campaign, the CFIS was exposed for 10 days, while spot samples were collected on the first and the last days of the campaign. Analysis results showed better sensitivity of the CFIS and good agreement between the results of CFIS and spot sampling. Therefore, the CFIS proved to be an efficient, sensitive and cost-effective alternative for monitoring organic pollutants in surface waters.

Application of miniaturized cell-based bioassays for high-throughput effect-directed analysis of passive sampler extracts using microfractionation
N. Zwart, VU University Amsterdam; T. Hamers, VU University Amsterdam, Institute for Environmental Studies (IVM) / Institute for Environmental Studies; W. Jonker, VU University Amsterdam / BioMolecular Analysis group; C.J. Houtman, The Water Laboratory; G. Somsen, VU University Amsterdam / BioMolecular Analysis group; J. de Boer, VU University Amsterdam / Institute for Environmental Studies; J. Kool, VU University Amsterdam / BioMolecular Analysis group; M. Lamoree, VU University Amsterdam / Institute for Environmental Studies
Routine monitoring of drinking water sources for endocrine disrupting chemicals is commonly limited to the determination of known priority substances through chemical analysis. With the ever changing composition of the mixtures of compounds in the environment, other potentially hazardous chemicals remain undetected. Efforts to keep track of the release of potential endocrine disruptors into the environment and to monitor the processes of drinking water purification depend on the ability to determine the presence of these compounds in surface, ground and effluent water. The advent of cell-based reporter bioassays allowed detection of active toxicants in mixtures based on their biological activity. The application of these bioassays together with analytical identification methods in effect-directed analysis (EDA) provides a strategy to detect and identify novel endocrine disrupting chemicals. However, for rapid toxicity assessment of e.g. water samples, EDA suffers from lack of throughput and is regarded as a laborious, time consuming method. To achieve higher-resolution separation and faster analysis on multiple end-points, a high throughput-EDA (HT-EDA) method was developed through application of UPLC based microfractionation in combination with a battery of miniaturized 384-well plate cell-based reporter assays performed in parallel. The applicability of this approach will be demonstrated by analysis of selected extracts from partitioning based silicone rubber (SR) passive samplers and adsorption based Speedisk passive samplers. The application of high-resolution microfractionation together with miniaturized bioassays will open the way to HT-EDA and will emphasize the advantages of the unification of chemical analysis and bioassays in the analysis of environmental samples, including drinking water.

Antibiotics and Antibiotic Resistance in the Environment: Ecological Fate and Effects, Resistance Development and Implications for Human Health

427
Co-selection for antibiotic resistance by biocides in the aquatic environment
L. Zhang, University of Exeter Medical School / The European Centre for Environment and Human Health; A. Murray; J. Snape, AstraZeneca UK Ltd. / AstraZeneca Global Environment; W. Gaze, The University of Exeter / Medical School
Antibiotic resistance is a growing problem in the treatment of clinical infections, leading to predictions that we are about to enter a post-antibiotic era where many bacterial infections are untreatable. Increasing attention is being placed on the environment as a reservoir of antibiotic resistant bacteria and in the potential for antibiotic residues and other compounds to select or co-select for antibiotic resistance. Quaternary ammonium compounds are used as biocides and are found in a wide range of personal care products, reaching mg/Lconcentrations in waste water. Work by Gaze et al. (2005) was the first to demonstrate co-selection by quaternary ammonium compounds (QACs) for antibiotic resistance in the environment. Recent work has shown that high QAC exposure selects for QAC resistance mechanisms that have also been implicated in resistance to antibiotics. Functional metagenomic libraries were screened for resistance to biocides, and transposon mutagenesis used to identify and sequence novel biocide resistance genes. Current work focuses on selection for QAC resistance and co-selection for AMR in experimental microcosms, to determine the minimal selective concentration (MSC) of QACs that co-select for antibiotic resistance. Data suggests QAC concentrations in highly polluted waste streams are in the same order of magnitude as the MSC.

428
Selection for antibiotic resistance in the environment
A. Murray; L. Zhang, University of Exeter / Medical School; J. Snape, AstraZeneca UK Ltd. / AstraZeneca Global Environment; W. Gaze, The University of Exeter / Medical School
Antibiotic resistant bacteria are a significant threat to both human health and the global economy. As few new antibiotics are currently in development, antimicrobial stewardship is currently the best strategy to avoid progression into a ‘post-antibiotic era’, a world in which most modern medical and farming practices will be unviable, and routine infections could once again become deadly. Most

mitigation strategies implemented thus far have focused primarily on intervention at the clinical level, and the role of the natural environment has been largely overlooked. However, it is known that the environment is not only a reservoir of clinical resistance genes and that these can be mobilised into human pathogens, but that resistance genes and antibiotics are constantly being introduced into the environment via several sources including waste water treatment plant effluent and run off from agricultural land. A key study by Gullberg *et al*. (2011) demonstrated that selection for resistance can occur at extremely low (potentially environmentally relevant) antibiotic concentrations, and therefore the environment may even be a platform for selection for resistance *in situ*. However, there are currently no standardised methods in practice which can estimate the effect concentrations of antibiotics in the environment, in terms of selecting for, maintaining, or mobilising resistance genes. Therefore mitigation strategies have been unable to be designed. In this study natural, complex communities were exposed to varying concentrations of antibiotics and resistance gene prevalence quantified by real time PCR. Antibiotic concentrations were chemically quantified and antibiotic degradation curves generated to determine the optimal culturing conditions to emulate continuous exposure at clinical and subclinical concentrations. The primary aim of this research is to understand how resistance may be selected for in the environment, and to design an assay which can be used for environmental risk assessment.

429

Impact of dairy manure pre-application treatment on dynamics of antibiotic-resistance genes in crop production systems

E. Topp, Agriculture and Agri-Food Canada (AAFC); B. Li, Graduate School at Shenzhen, Tsinghua University; T. Zhang, University of Hong Kong

Antibiotics are widely used in livestock and poultry production for growth promotion, prophylaxis and treatment of illness. There is a widespread concern that this practice promotes resistance and erodes the efficacy of antibiotics used in human medicine, a crucially important public health challenge. The recycling of animal and poultry wastes into crop production systems to recycle valuable nutrients and improve soil quality is widely practiced. However, a reservoir of antibiotic resistance genes in the environment that is made larger through contamination with agricultural wastes may represent an enhanced threat to human health. In the present study, we sought to determine if pre-treatment of dairy manure through composting, dewatering, or anaerobic digestion would alter the loading rates of antibiotic resistance genes, their persistence in soil following application, and the burden of antibiotic resistance genes on crops at harvest. Experiments were undertaken during the 2014 growing season on the Agriculture and Agri-Food Canada research farm in London, Ontario, Canada. Manure for applications in the spring of 2014 was obtained from two local dairy farms. One farm supplied the raw manure slurry, and anaerobically digested manure digestate. The second farm supplied the mechanically dewatered, and the composted manures. Replicated field plots received no manure (ie. untreated control), raw, composted, dewatered or anaerobically digested dairy manure. Plots were planted to carrots, radish, or lettuce. DNA was extracted from manures, soils throughout the growing season and vegetables at harvest. These were variously analyzed by straight PCR, quantitative PCR, or high throughput sequencing to establish the loading rates, soil persistence, and exposure of vegetables to selected gene targets associated with antibiotic resistance or gene mobility. Composted manure had the lowest abundance of gene targets, whereas anaerobic digestate that the highest. There was no consistent effect of manure pre-treatment on persistence of gene targets in soil following manure application. Referenced to vegetables grown in ground without manure there was no consistent increase in gene target abundance on vegetables grown in manured ground.

430

Fate of antibiotics into agricultural soils amended or not with organic waste products, and combined effects of contaminants

A. Andriamalala, UMR ECOSYS; L. Vieublé-Gonod, INRAAgroParisTech / UMR ECOSYS; P. Cambier, UMR ECOSYS

Antibiotics (ATB), widely used in human and veterinary medicine, are for the most part excreted. Waste water treatments do not eliminate them completely. Consequently, spreading organic waste products (OWP) issued from sewage sludge or liquid and solid manures may disseminate ATB in soils with unknown risks for human health and environment. In addition, these OWP contain other contaminants such as trace metals (TM), which tend to accumulate in soils submitted to repeated spreadings. Interactions between contaminants may affect the fate or and the potential effects of ATB.\nOur objectives were to investigate the impact of soil type and combinations of ATB and TM on the degradation of two ATB in soils, ciprofloxacin (CIP) and N-acetyl-sulfamethoxazole (N-SMX). Cu and Zn were chosen as TM. Soil incubations of 14C labelled ATB under laboratory conditions were used to quantify over time their fate and distribution in the soil (mineralized fractions, easily and hardly extractable fractions, and non-extractable fraction).\nThe influence of the type of soils was studied from applications of N-SMX (0.02 mg / kg) or CIP (0.15 mg/kg), on three agricultural soils likely to harbour a microflora more or less adapted to degradation of ATB: a control, unamended soil and two soils amended every two years since 1998 respectively with a compost of sewage sludge/green waste and with farmyard manure. Results showed that the N-SMX mineralization was low, in the order of 10% after 150 days, whereas mineralization of the CIP was negligible. The majority of the radioactivity was concentrated in the hardly extractable and non-extractable fractions. The fate of these ATB has been barely affected by soil type.\nThe impact of combined inputs of N-SMX and TM on the fate of N-SMX was studied through applications of N-SMX alone (0.02 mg/kg) in the control soil, or in a solution of copper and zinc, at realistic doses (respectively 20 and 30 mg/kg) and at five times this dose (respectively 100 and 150 mg/kg). The presence of metals provided at the highest dose resulted in a decrease in mineralization and an increase in adsorption, attributed to a direct effect of metal (complexation with N-SMX and inhibition of the activity of certain microorganisms) and to an indirect effect via a decrease in pH.

431

Adsorption and ecotoxicity of three pharmaceuticals: cocktail effect

R. SMITH, ChampagneArdenne; S. Sayen, University of Reims Champagne-Ardenne; G. Emmanuel, Université de Reims Champagne Ardenne; F. GERET, Centre Universitaire JeanFrançois Champollion Albi France

Pharmaceuticals are a class of emerging contaminants whose production has increased for many years andwhich are emitted in large amounts to the environment *via* different pathways (wastewater treatment plants effluents, sludges, manure…). They are continuouslydetected in the environment because their rate of removal is compensated by the daily input of new molecules, and they present a risk of toxicity for non-target organisms and human health. In the environment, they are present as mixtures of compounds and they coexist with other pollutants such as, for example, metallic trace elements. Nowadays, there is a lack of information about their behaviour when present in mixtures and about the potential interactions between the different compounds (cocktail effect).Indeed, metals canfor example interact with pharmaceuticalsin particular throughthe formation of complexes which may affect theirbehaviourin the environment. Among the processes governing the fate of pharmaceuticals, adsorptionprocesses play a key role controlling their mobility and bioavailability to organisms in soil and water compartments. It is thus necessary to bring knowledge about their behaviour at solid/water interfaces and their toxicity towards organisms considering the cocktail effect in order to design more realistic scenarios. The aim of this work is to bring knowledge about the behaviour in the environment of three pharmaceuticals considering their cocktail effect: sotalol (a beta-blocker), furosemide (a diuretic) and sulfamethoxazole (an antibiotic).We present in this study (i) their adsorption behaviour on a selected soil as a function of concentrations, which is needed to define the mobility of the compounds and to precise at which extent they are available to organisms, and (ii) their toxicity on two aquatic organisms (*Vibrio fischeri*, and *Daphnia magma* at different concentrations. In each case, we studied the behaviour of each molecule taken separately and of mixtures containing the three pharmaceuticals. In addition, the influence of the presence of copper(II), an ubiquitous metallic cation, was also considered. **Keywords**: adsorption, toxicity,pharmaceuticals, metals.

432

Occurrence and environmental risk assessment of selected antibiotics and antiretroviral drugs in Nairobi River Basin, Kenya

E.K. Ngumba, University of Jyvaskyla / Biological and Environmental Science; T. Tuhkanen, University of Jyvaskyla / Biological and Environmental Sciences; A. Gachanja, Jomo Kenyatta University of Agriculture and Technology / Chemistry

In this study, we investigated the occurrence of three antibiotics (sulfamethoxazole, trimethoprim and ciprofloxacin) and three antiretroviral (lamivudine, nevirapine and zidovudine) drugs in Nairobi River Basin, Kenya. The analytical procedure involved extraction using solid phase extraction followed by liquid chromatography-electrospray ionization tandem mass spectrometry (SPE-LC-ESI-MS/MS). In the study, 40 sites were selected for sampling, including 38 sites along the rivers and 2 wastewater treatment effluents sites. All the studied compounds were detected with sulfamethoxazole having the highest detection frequency of 97.5% and ciprofloxacin had the lowest at 60%. The results showed that the concentration of the drugs increased in highly populated regions especially within the informal settlements. The maximum (median) concentration in the river waters for sulfamethoxazole, trimethoprim, ciprofloxacin, lamivudine, nevirapine and zidovudine in ng/L were 13800 (1800), 2650 (327), 509 (129), 5430 (1000), 4860 (769), and 7680 (660), respectively. The maximum concentrations in the river waters were generally higher than those of the wastewater treatment plant effluents signifying that the rivers are substantially contaminated by domestic wastewater. The environmental risk was evaluated by calculating the risk quotients (RQs) for algae, daphnia and fish based on the maximum and median concentrations of the analytes in the river basin and was expressed as the ratios of measured environmental concentrations (MEC) to predicted no effect concentrations (PNEC). The RQs ranged from 0–507.8 and apart from lamivudine that had a low RQ, all the other analytes had RQ>1 at maximum and median measured concentrations for at least one taxonomic group. The high RQs are indicative of possible adverse ecological effects and calls for corrective and mitigation strategies. Key words: Antibiotics, antiretroviral, occurrence, risk

Pushing nanoparticle studies to the limit - working at environmentally relevant concentrations and with complex matrices (III)

433

Changes in the metabolome of Mytilus galloprovincialis exposed to fullerene aggregates under environmentally relevant conditions

J. Sanchís, IDAEA-CSIC / Water and Soil Quality Research Group; C. Bosch, IDAEA-CSIC / Environmental Chemistry; m. llorca, Institute of Environmental Assessment and Water Research; M. Olmos, IDAEA-CSIC / Water and Soil Quality Research Group; G.F. Schirinzi, M. Farre, IDAEA-CSIC; D. Barcelo, IIQAB-CSIC / Dept Environmental Chemistry

The environmental study of nanomaterials has been a thriving topic during the last years because of their high number of potential emission sources; unique transport and distribution patterns, different to those of the conventional micropollutants; and the high uncertainty around their ecological effects. Among them, fullerenes have received a particular attention and their presence in rivers [1,2], soils [3], wastewater effluents [4] and air particulate [5] has been recently characterized. Because of their particular colloidal behaviour the properties and toxic effects of fullerenes in experiments at lab-scale are highly influenced by the dispersion method and physico-chemical properties of the medium. Therefore, conducting experiments simulating conditions similar to those observed in the real environment is crucial in order to create aggregates with realistic toxic effects and results that are translatable to the real environment. In the present work fullerenes were dispersed and aged in artificial estuary water (with controlled ionic strength, pH and humic acid content) by means of long time stirring with air and sunlight exposure. The suspensions were characterized by means of scanning electron microscope and nanoparticles tracking analysis. The obtained suspensions were employed in metabolomic experiments involving Mediterranean mussels (*Mytilus galloprovincialis*). The exposition was carried out in marine mesocosms of 450 l with pristine seawater at sub-ppb concentration levels. The metabolomic profile of the exposed mussels was analyzed by LC-ESI-HRMS with hybrid qudrupole-Orbitrap analyser in data-dependant scan acquisition mode. Several time-dependant changes were observed in the tested organisms, including changes in the lipid composition, changes in the aminoacids profile and the appearance of oxidative stress biomarkers, such as ophthalmic acid. Overall, the results are consistent with an oxidative stress response, which is observed even at sub-ppb concentrations at metabolic level and that raises questions about the chronic toxicity of these emerging contaminants. Assessing the heteroaggregation of manufactured nanoparticles with naturally occurring colloids in a typical surface water

D. Slomberg, Labex Serenade/CEREGE/Aix-Marseille Université; J. Labille, CNRS; A. Praetorius, University of Vienna / Department of Environmental Geosciences; C. Harns, University of Wyoming; J. Bottero, Labex Serenade/CEREGE/Aix-Marseille Université; P. Ollivier, BRGM; M. Scheringer, N. Sani-Kast, ETH Zurich / Institute for Chemical and Bioengineering; S. Ilina, BRGM; J. Brant, University of Wyoming

To assess the risk posed by nanotechnology-enabled products, the likelihood of engineered nanoparticle (NP) exposure through aqueous media must be considered, as it is a receptacle of these materials throughout their lifecycle. The predicted concentrations of engineered NPs in surface water systems are expected in the μg/L level for nano-TiO_2, and consequently, in real aquatic systems, the probability that NPs interact with each other may be lower relative to their collision frequency with naturally occurring colloids present at substantially higher concentrations (mg/L to g/L). Due to the high specific surface area and reactivity of colloids, they may strongly affect the fate and transport of NPs via heteroaggregation processes. Thus, fate models aimed at predicting NP behaviour and concentration profiles must account for this heteroaggregation. A NP-colloid sticking efficiency, α_{hetero}, is well suited as an input for such fate models, but remains a challenge to determine experimentally. Here, we present a novel method for determining α_{hetero} at environmentally relevant NP concentrations by using a combination of laser diffraction measurements and aggregation modeling based on the Smoluchowski equation. Interactions between TiO_2 NPs (15 nm) and different types of larger mineral colloids (i.e., silica microspheres, smectite clay, and natural riverine suspended particulate matter) were used to demonstrate this new approach. Studies were conducted at low NP concentrations (0.1 to 4 mg/L) with regard to the colloid occurrence (100 mg/L) to develop realistic fate scenarios for surface water systems. The NP/colloid number ratio was found to be a critical component in the heteroaggregation mechanism and the effects of ionic strength, pH, and natural organic matter on NP heteroaggregation were also explored. Our data show that at relevant concentrations, NP behaviour is mainly driven by heteroaggregation with colloids, while homoaggregation remains negligible. The dimensionless α_{hetero} value is a key parameter needed to feed environmental fate models that are of high importance in the field of risk assessment of engineered NPs, as they contribute to better predict the exposure aspect in aqueous systems with continuously increasing relevance. Effect of surface coating on nanoparticle stability and fate in high strength electrolytes - silver nanoparticles in marine waters

D. Lyons, Center for Marine Research; M. Levak, P. Buric, D. Jurasin, M. Dutour Sikiric, N. Mikac, Rudjer Boskovic Institute; F. Meier, R. Welz, Postnova Analytics Inc

Much of the early work on the characterisation of nanomaterials focused on pristine nanomaterials in simple matrices such as ultrapure or freshwater. Characterisation of nanoparticles in more complex matrices such as physiological fluids has not had the same level of attention paid to it and analysing nanoparticles in such matrices remains a significant challenge. While some methods for the extraction of nanoparticles from confounding matrices have been brought to bear, they are relatively harsh leading to the nanoparticles or their (bio)surface coating being modified as a result of the extraction process. Hence, the characteristics of extracted nanoparticles that are ultimately determined are not the same as when they were originally in the matrix. This has a critical impact on toxicity studies as these extracted nanomaterials are ultimately only proxies for the original biological identity of the nanomaterial that would have been encountered by living organisms. To investigate the role of a bio-corona in a complex matrix, we have studied bovine serum albumin-coated silver nanoparticles as a proxy for probing the impact of a bio-coating on nanoparticle behaviour and fate in high strength electrolyte solutions. We have found that bovine serum albumin (BSA) stabilizes silver nanoparticles in high strength electrolytes, with the stabilisation effect increasing with both ionic strength and BSA concentration. The ion release kinetics of the dissolution of silver nanoparticles is significantly lower in the presence of BSA and may be related to BSA suppressing ion release or acting as a store for silver ions and hence the measured quantity of ions released in solution is misleading. Thus understanding the impact of a bio-corona on nanoparticle behaviour in complex matrices is a key preliminary factor that must be considered when modelling nanoparticle fate and investigating their toxic potential in real life scenarios.

Extrapolated long-term stability of titanium dioxide nanoparticles and multi-walled carbon nanotubes in artificial freshwater

A. Brunelli, University Ca Foscari of Venice; A. Zabeo; E. Semenzin, Ca Foscari University of Venice / Department of Environmental Sciences Informatics and Statistics; D. Hristozov, Ca Foscari University of Venice; A. Marcomini, University of Venice / Department of Environmental Sciences Informatics and Statistics

The potential environmental release and the resulting exposure to engineered nanomaterials (ENM) along their life cycle are expected to constantly increase (Nowack et al., 2012; Pettitt and Lead 2013). Based on environmental exposure scenarios, water is one of the main compartments where ENMs can be released (Nowack et al., 2014). Similar to colloidal particles, upon release into the environment, intrinsic physico-chemical properties of ENMs as well as the specific environmental conditions mainly determine fate and behavior of ENM (Hartmann et al., 2014). Therefore, a comprehensive characterization of all the processes affecting the ENMs system stability is needed. Among all, transformation processes, such as surface modification, homo- and hetero-aggregation, and transport processes, i.e. advection and sedimentation, have been identified as key factors to affect fate and behavior of ENMs in the aquatic environment (Quik et al., 2014). In this work, long-term stability of ENMs, i.e. the inorganic n-TiO_2 P25 and the organic Multi-Walled Carbon Nanotubes (MWCNTs) NC7000, dispersed in artificial freshwater (5-100 $mg \cdot l^{-1}$), was investigated by extrapolation from short-term stability experiments. Hydrodynamic diameter and ζ-pot, calculated by means of Dynamic and Electrophoretic Light Scattering, respectively, qualitatively indicated a general ENMs dispersions instability over 1 h time. Sedimentation results, obtained by Centrifugal Separation Analysis using the LUMiSizer over approx. 30 min of analysis, allowed to estimate the quantitative long-term (over 30 days) stability of ENMs. Settling data fitted satisfactorily with a first order kinetic equation (R^2 in the range of 0.918-0.989). The extrapolated settling rate constant *k* values at gravity spanned one order of magnitude, i.e. from $7.21 \cdot 10^{-5}$ to $4.12 \cdot 10^{-4}$, and increased with the increasing of initial ENMs concentration. Sedimentation velocities were in good agreement with those reported in literature ($7.8 \cdot 10^{-2}$ - $1.7 \cdot 10^{-1}$ $m \cdot d^{-1}$ vs. $5 \cdot 10^{-4}$ - $3 \cdot 10^{-1}$ $m \cdot d^{-1}$ for n-TiO_2 and $5.9 \cdot 10^{-2}$ - $3.4 \cdot 10^{-1}$ $m \cdot d^{-1}$ vs. $2 \cdot 10^{-1}$ – 1.2 $m \cdot d^{-1}$ for MWCNTs). n-TiO_2 showed a higher long-term stability with respect to MWCNTs (average: $1 \cdot 10^{-1} \pm 3.4 \cdot 10^{-2}$ $m \cdot d^{-1}$ instead of $1.7 \cdot 10^{-1} \pm 1.1 \cdot 10^{-1}$ $m \cdot d^{-1}$, respectively).

Assessing the detection limits of multi-isotopically labelled CdSe/ZnS quantum dots in natural and biological environments

N. Supiandi, Institut de Physique du Globe de Paris / Geochimie des Eaux; Y. Sivry, IPGP - VAT FR79197534282; G. Charron, Université Paris Diderot; M. Tharaud, Institut de Physique du Globe de Paris, Sorbonne Paris Cité, Univ. Paris Diderot; L. Cordier, IPGP; J. Guigner, IMPMC; A. Gelabert, IPGP; N. Menguy, IMPMC; M.F. Benedetti, Université Paris Diderot

The vast majorities of NPs-related studies presented in the literature are carried out in conditions far from those in real environmental medium [1] (water, soil, sediment). In particular, the high concentrations (>1 mg/L) of nanoparticles (NPs) used in experimental studies are related to the difficulty of detecting nanoparticles in complex and "noisy" natural and biological environments. However, changes in NPs concentration can affect its physicochemical behavior (ex: solubility, aggregation) and thus the final interpretation and understanding of results. In order to overcome analytical barriers while working at representative realistic concentration, innovative tools such as HR-ICP-MS and non-traditional stable isotopes (isotopically modified NPs [2] or "spiked") have been used. 7 nm sized isotopically labelled quantum dots (QDs), CdSe/ZnS core-shell structure were synthesized, enriched in ^{68}Zn, ^{77}Se and ^{111}Cd. They were disseminated at very low concentrations (0.1 ng/L to 5 μg/L) in both aquatic and biological matrices and then analyzed by HR-ICP-MS (ThermoScientific Element II) based on the protocol described by Dybowska et al. [3]. Preliminary results allowed to assess the detection and quantification limits of spiked QDs in complex matrices such as river water or saliva and plasma. The feasibility of isotopic labeling at very low concentrations has been demonstrated: spiked Zn, Cd and Se issued from QDs were quantifiable at 10, 3 and 20 ng/L respectively in a media not containing the same natural elements, and at 1000, 150 and 1000 ng/L in saliva, and at 50 ng/L of spiked Zn in Seine river water. The results obtained in this experimental work are applicable for studying QDs fate and behavior in most aquatic and biological media.

Fish model species in environmental toxicology

Addressing whether roach in English rivers have adapted to the harmful effects of exposure to oestrogenic wastewater treatment work effluents

P. Hamilton, University of Exeter / Biosciences; A. Lockyer, Brunel University; A. Baynes, Brunel University / Institute for the Environment; T. Uren Webster, University of Exeter / Biosciences College of Life and Environmental Sciences; E. Nicol, Brunel University / Institute for the Environment; N. Beresford, Brunel University; G. Harris, Brunel University / Institute for the Environment; G. Drinkwater, Brunel University; D. Studholme, J. Stevens, University of Exeter; S. Jobling, Brunel University; C. Tyler, Biosciences College of Life and Environmental Sciences

Wastewater treatment work (WWTW) effluents comprise a large proportion of the flow of lowland rivers across the world. Many WWTW effluents are oestrogenic and induce a range of feminised phenotypes in wild male fish including the intersex condition – the presence of developing eggs in the testes of otherwise male fish. In UK rivers, the reproductive success of the most feminised male roach (*Rutilus rutilus*) is reduced by up to 76%. However, population genetic analyses have identified some populations of roach that have been largely restricted to stretches of river with a high proportion of oestrogenic effluent over multiple generations. This raises the question of whether roach can, and have, adapted to the harmful effects of exposure to oestrogens. To investigate this, we are searching for footprints of selection by analysing single nucleotide polymorphisms (SNPs) in wild roach populations; in tandem with an experimental approach, to examine differences in oestrogen sensitivity. We assembled a transcriptome for roach and used it to identify SNPs in a suite of oestrogen-responsive genes including aromatases, oestrogen receptors and vitellogenins. Genotyping wild roach populations derived from four effluent contaminated rivers (Lee, Foss, Aire and Mole) and five other river stretches that receive little or no effluent using this SNP panel revealed variation in oestrogen-responsive genes, and we are currently investigating patterns of selection in these genes. Analysis of SNPs derived from restriction-site associated DNA (RAD) tag genotyping of roach from the polluted River Lee and nearby clean river Cuffley Brook identified diverse genes with signatures of selection including several that are related to regulation of cell growth and DNA repair in humans. Functional annotation in DAVID identified two overrepresented GO terms: metal ion binding and exposure to organic substances, both consistent with the view that exposure to chemical pollution has acted as a selective pressure on roach in the River Lee. We have also conducted a 2 year exposure to 1.8 ng/L ethinyloestradiol (EE2) to compare sensitivities of the offspring of roach from different rivers. Exposure resulted in a range of gonadal phenotypes in male fish; from fish with normally developed gonads to those with both male and female gametes (intersex) and an ovarian cavity. We are now comparing feminised responses between fish from different rivers.

Integrating biotic factors in toxicokinetic modelling of metal accumulation in fish

Y.T. Le, M. Nachev, D. Grabner, University of DuisburgEssen / Aquatic Ecology; J. Hendriks, Radboud University Nijmegen / Department of Environmental Sciences; B. Sures, University of Duisburg Essen / Aquatic Ecology

Fish are exposed to both pollutants and parasites. Parasites might affect the toxicity of pollutants like metals. So it is important to consider parasitism in modelling metal accumulation in fish. Toxicokinetic (one- or multi-compartment) models have been used for simulating metal accumulation in aquatic organisms. The multi-compartment model allows for predicting tissue-specific concentrations, but requires a larger number of parameters. We developed a one-compartment model and a multi-compartment model (covering blood, storage, gills, kidney, liver, intestine, and gallbladder) simulating metal accumulation in the chub *Squalius cephalus* uninfected and infected with the acanthocephalan *Pomphorhynchus laevis*. In models for the uninfected chub, uptake toxicokinetics was related to species weight and metal properties while the absorption efficiency and elimination rate constants were parameterised based on published data. For the infected chub, physiological parameters were parameterised from the value for the uninfected. Tissue-blood partitioning in the multi-compartment model was calibrated using published data on ^{210}Pb accumulation overtime, but not validated. The one-compartment model was validated using data set on Pb concentrations in the whole fish at the end of exposure experiments. Predicted concentrations of Pb in the fish-parasite system by the one-compartment model were significant related to the measured. The estimates were generally within one order of magnitude of the measurements. Moreover, the predictions of Pb accumulation in the system were more sensitive to the absorption efficiency than to the elimination rate constant. For the multi-compartment model, preliminary calibration results show high tissue-blood partitioning in liver and intestine, consistent with their role in detoxification, and effects of parasites on the tissue-blood partitioning in liver and intestine. Modelled concentrations of ^{210}Pb in all fish organs were generally within one order of magnitude of the measured. Stable concentrations in storage and increasing concentrations in intestine and gallbladder of the uninfected chub could be explained by the model. The stability in ^{210}Pb accumulation in storage and fluctuation in gills of the infected chub are consistent with modelled patterns. Yet, increasing concentrations in gills and liver of the uninfected and fluctuating concentrations in intestine and gallbladder of the infected could not be simulated by the model.

Ecotoxicological impacts of cyanobacteria on fish: effects of chronic exposure of medaka fish to cyanobacteria-dominant conditions

S. Le Manach, UMR Molécules de communication et adaptation des microorganismes; H. Huet, ENVA; B. Sotton, C. Duval, M. Edery, S. Zirah, B. Marie, MNHN / UMR Molécules de communication et adaptation des microorganismes

The interactive effects of eutrophication and climate change may promote cyanobacterial blooms in continental aquatic ecosystems, which pose potential risks to fish ecology and ecosystem sustainability. To date, more than 600 cyanobacterial compounds potentially toxic have been described from various taxa. These cyanotoxins can be released by cyanobacteria into the water leading to potential toxic effects to aquatic organisms. Among the various families of cyanotoxins, two classes of metabolites have attracted more attention due to their toxicity: the hepatotoxins such as microcystin (MC) and the neurotoxins. Furthermore, during the past decades, many bioactive peptides and alkaloid groups have also been discovered, as the classes of aeruginosins, microginins, cyanopeptolins and anabaenopeptins which could present also potential deleterious effects on aquatic organisms. Since cyanobacteria can produce and release mixtures of cyanotoxins rather than just single toxins, a better understanding of the production and the toxicity of this diversity of metabolites is necessary. While several works reported the toxicological effects of single cyanotoxins, only few have discussed the importance of an environmental context. A method of chronic exposure of a fish model (medaka) to cyanobacteria in an environmental relevant context was developed in this study. Female and male medaka fish were exposed by balneation during 21-days to 4 treatments: i/ Control, ii/ Non-MC producing culture, iii/ MC producing culture extracts and iv/ MC producing culture. The aim of this study was to investigate the cellular and molecular ecotoxicological effects of cyanobacterial blooms in order to better understand their potential impacts on fish, through the use of histologic examinations and "Omics" approaches in fish liver. Interestingly, our results show the immunolocalization of microcystins in the gut and the liver of microcystin-producing cyanobacteria-treated fish, but not in fish treated by other conditions. In addition, quantitative proteomics by iTRAQ 8-plex labelling and metabolomics by Nuclear Magnetic Resonance (NMR) highlighted clear metabolic differences according to gender and treatments. This work will give a first insight of effects of genuine cyanobacteria bloom on medaka fish in an environmental context and highlights the importance of taking in consideration living cells rather than extracts in fish exposition, approaching the actual conditions of aquatic systems.

A novel ZF-Tox-Array to identify toxicity of environmental contaminants

and complex mixtures

J. Legradi; P. Cenijn, J. Koning, Vrije Universiteit Amsterdam / Institute for Environmental Studies; j. kamstra, NMBU / BaSam; M. Lamoree, VU University Amsterdam / Institute for Environmental Studies; T. Hamers, VU University Amsterdam, Institute for Environmental Studies (IVM) / Institute for Environmental Studies; J. Legler, Vrije Universiteit Amsterdam / Institute for Environmental Studies

There are over 100,000 chemicals on the market, many of which end up in the environment as complex mixtures. The current chemical-by-chemical approach to environmental quality assessment has significant limitations, as only a limited number of chemicals can be assessed. Testing or monitoring single chemicals also does not address the complexity associated with mixtures. There is growing public concern about the risks associated with low levels of highly potent chemicals such as drugs, hormones and pharmaceuticals which end up in the environment via waste streams. Therefore, other sensitive methods are needed to assess the risk of chemicals in general and certainly when they are present in complex mixtures, like in the environment. Here, we aim to provide a new sensitive genomics-based tool for safety assessment of chemicals and complex mixtures. Therefore we developed ZF-Tox-Array, a combination of state of the art multiplex qPCR and zebrafish (*Danio rerio*) toxicity testing, as a new cost-effective, sensitive effect-based approach to screen chemicals and environmental samples for their toxicity. With the ZF-Tox-Array, multiple toxic modes of action (MoA) can be assessed in parallel compared to standard applied *in vitro* assays which are mostly specific for only one MoA. Our new system allows to screen up to 42 target genes, covering several toxicity pathways in parallel. Based on literature, target genes were selected known to be involved in commonly assessed toxicity pathways was made. MoA covered general stress, apoptosis, oxidative stress, DNA damage, metabolism, metabolism phase II/III, endocrine disruption, adipogenesis, insulin signaling and neurotoxicity. A great advantage of our ZF-Tox-Array system is the flexibility as the list of target genes can be adapted to a variety of MoA of interest. The ZF-Tox-Array system was first validated and optimized using model substances. In the next step we applied our new system to screen 39 environmental pollutants for their neurotoxic potential using a special set of neurotox target genes. In an additional study we selected 42 target genes covering different MoAs that are commonly studied with water risk assessment and screened different drinking, surface and waste water samples for their toxicity. Our study shows that even at concentrations where no visual malformation can be seen strong gene expression changes can be observed and that new toxic insights can be gained by using ZF-Tox-arrays.

442
Stickleback FET test with gene expression analysis can detect endocrine disrupting chemicals

H. Watanabe, National Institute for Environmental Studies / Center for Environmental Risk Research; T. Bean, M. Sebire, Centre for Environment Fisheries and Aquaculture Science / Environment and Animal Health; T. Williams, University of Birmingham / School of Biosciences; P. Antczak, University of Liverpool / Institute of Integrative Biology; I. Katsiadaki, Centre for Environment Fisheries and Aquaculture Science / Environment and Animal Health

The three-spined stickleback (*Gasterosteus aculeatus*) is a useful sentinel species in chemical risk assessment, particularly for detecting endocrine disruptors (EDs). As with zebrafish, the fish embryo toxicity (FET) test using stickleback needs to be developed as an alternative to adult fish test in compliance with animal welfare. Gene expression analysis following FET test can provide an insight on the signalling pathway responding to chemicals and as such can provide an early warning for downstream effects. To understand the differences in transcriptional response to chemicals between adult fish and embryos, we performed global gene expression analysis of the embryos using microarrays (Agilent-029767) following FET test. In the FET test, we exposed fertilized stickleback eggs to the 6 single chemicals (cadmium, dibutyl phthalate, fluoxetine, ibuprofen, 17α-ethynylestradiol(EE_2) and levonorgestrel) and 6 mixtures, each consisting of 5 chemicals for 10 days (the time needed for the stickleback embryo to reach the self-feeding stage). The microarray results were compared with those obtained from adult fish liver after 4 days of exposure. Our overall aim was to investigate if the fish embryos were capable of expressing at least partly the signalling pathway from molecular initiating event to adverse outcome and evaluate the potential replacement of adult fish by embryos. No. of genes statistically significantly expressed in 6 single chemicals from controls was as follows: $EE_2 = 3$, Levonorgestrel = 10, DBP = 875, Cd = 940, Ibuprofen = 1589, Fluoxetine = 0. Similar response was found after Cd, ibuprofen, and DBP exposure, suggesting typical chemical stress response (e.g. oxidative stress). For EE_2, estrogen related genes (vitellogenin, choriogenin) were upregulated as was previously found in adult fish. For levonorgestrel, the androgen related genes (spiggins) were upregulated, which was not observed in the liver of adult fish (spiggin is expressed only in the kidney of adult fish). Levonorgestrel antagonised the action of EE_2 by significantly reducing the expression of vitellogenins and choriogenins, whilst EE_2 antagionised the action of levonorgestrel by reducing the expression levels of spiggins. Both findings were identical to those observed using adult fish. These results indicate that the stickleback FET test is a useful screening assay for EDs, providing clear responses to both estrogenic and androgenic chemicals.

MetaOMICs in ecotoxicology: evaluation of alterations in the structure and functions of ecosystems

443
Next-Generation Sequencing to highlight community changes in river biofilms linked to pharmaceutical loads from a wastewater treatment plant

T. CHONOVA, C. CHARDON, F. KECK, INRA UMR CARRTEL; J. LABANOWSKI, E. LAURENT, L. MONDAMERT, Université de Poitiers; B. MONTUELLE, INRA UMR CARRTEL; F. RIMET, INRA UMR CARRTEL / UMR CARRTEL; V. VASSELON, INRA UMR CARRTEL; A. Bouchez,

Hospital wastewaters contain wider spectrum and higher concentrations of pharmaceuticals than urban ones. Despite this, they are usually co-treated in traditional wastewater treatment plants (WWTP) which are not designed to remove specific hospital contaminants. Hence urban and hospital treated effluents may still contain residues of pharmaceuticals which are then released into the recipient aquatic environment and might cause environmental risk. Therefore, a better understanding of the effect of pharmaceuticals in the environment is required. Biofilms are effective “biological sensors” for assessing the environmental effects of pharmaceuticals due to their ability to respond rapidly to physical, chemical and biological fluctuations by changes in their structure and composition. The use of Next-Generation Sequencing (NGS) allows a deeper and more accurate characterization of changes in the community structure. This is helpful to describe specific adaptations of bacterial and algal communities to the presence of pharmaceuticals and thereby disentangle multiple stress effects in environmental studies. Environmental biofilms were colonized (6 times from Feb to July 2014) at the output of a wastewater treatment plant 1/ in separately treated effluents from urban and hospital wastewaters and 2/ in the recipient river (River Arve, French Alps) up- and downstream from the WWTP output. A joined monitoring of environmental abiotic factors (SIPIBEL observatory) and pharmaceuticals (POCIS) was performed. NGS, using PGM Ion Torrent technology, was used for in-depth characterization of the composition of diatoms and bacterial communities in the biofilms through a metabarcoding approach based on rbcL and 16S rRNA amplicons, respectively. Concentrations of pharmaceuticals were higher in hospital than in urban effluents. Lower concentrations were observed in the river than in effluents, although higher downstream than upstream the WWTP output. NGS sequencing showed strong differences between microbial biofilm communities developed in all 4 sites, together with a clear seasonal effect. However local similarities were stronger than seasonal ones, revealing the strong impact of the wastewater effluents in shaping the environmental communities. Finally, the assessment of community composition using NGS, coupled to integrated measurement of pharmaceuticals, is efficient to highlight the disturbing effect of pharmaceuticals on environmental microbial communities.

Structure of microbial communities impacted by hydrocarbons in oxic/anoxic interface in coastal marine sediments

C. Noel, C. Cagnon, F. Terrisse, Université de Pau et des Pays de lAdour / IPREM EEM UMR CNRS; R. Duran, Université de Pau et des Pays de lAdour; C. Cravo-Laureau, Université de Pau et des Pays de lAdour / IPREM EEM UMR CNRS

Coastal marine sediments constitute unique functional ecosystems constantly subjected to oxic/anoxic oscillations according to tide cycles, bioturbation activities by macrofauna and other mechanical processes. Due to their location they are exposed to pollution injuries such as oil spills. Microbial communities play critical roles in global biogeochemical cycles in marine sediments, particularly in response to the presence of hydrocarbons. Thus, understanding the response of these key microorganisms exposed to hydrocarbons under oxic/anoxic oscillations provide pivotal information for estimating the resilience capacities of the ecosystem. Recently, we showed that the organization of hydrocarbon degrading bacterial communities was driven by sediment reworking activities (Stauffert *et al*., 2013). Indeed, three different microbial communities were obtained applying various reworking strategies but their overall degradation efficiency was similar highlighting the functional redundancy involved in hydrocarbons degradation. In order to further characterize the microbial assemblages, the three microbial communities were incubated in different oxygenation regimes (oxic, anoxic and oscillating conditions) in bioreactors. Then *Bacteria* and *Archaea* 16S rRNA transcript amplicons were analysed by high-throughput sequencing. Although PICRUSt functional analyzes (Langille *et al*., 2013) revealed that the three *Archaea* communities were different, they were not affected by the oxygenation conditions imposed in the bioreactors. In contrast, *Bacteria* communities were structured according to the oxygenation conditions. Correlation analysis showed that *Archaea*/*Bacteria* interactions, particularly the methanogens/sulfate-reducing bacteria relationships, are of primarily importance in the microbial communities assemblages in presence of hydrocarbons including the hydrocarbon degradation capacity. We thus suggest to carefully examine the *Archaea*/*Bacteria* interactions in microbial ecotoxicology studies to evaluate the impact of pollutants. Langille MGI, Zaneveld J, Caporaso JG, McDonald D, Knights D, Reyes JA, *et al*. (2013). Predictive functional profiling of microbial communities using 16S rRNA marker gene sequences. *Nat Biotechnol* **31**: 814–821. Large-scale shotgun metagenomics of periphyton communities exposed to triclosan

M. Eriksson, Chalmers University of Technology / Department of Shipping and Marie Technology; T. Österlund, Chalmers University of Technology / Mathematical Sciences; S. Abrahamsson, Chalmers University of Technology / Department of Mathematical Sciences; H. Johansson, N. Corcoll, University of Gothenburg / Department of Biology and Environmental Sciences; K. Sanli, University of Gothenburg / Department of Biological and Environmental Sciences; T. Backhaus, H. Blanck, University of Gothenburg / Department of Biology and Environmental Sciences; E. Kristiansson, Chalmers University of Technology / Department of Mathematical Statistics

High-throughput DNA sequencing has a great potential to detect effects from toxicants in natural communities. However, its potential in community ecotoxicology has so far not been realized. In this study we test if high-throughput Illumina shotgun sequencing can identify effects of the bactericide triclosan (TCS) in natural marine periphyton (biofilm) communities. We performed a long-term (17 days) flow-through microcosm experiment with natural marine periphyton. These communities are highly diverse and a large sequencing effort is needed to achieve a good sequencing depth. 4 replicate controls and 8 TCS exposure levels, covering a concentration range of 0.32-1000 nM with and triplicates of the 3.16 nM, 31.6 nM and 316 nM treatments, was included.Paired-end sequencing libraries was prepared with the TruSeq PCR-free kit and sequencing was done using the HiSeq 2500 Illumina sequencing platform. We generated 475 Gbases (1.9 billion DNA read pairs) of metagenomic sequence data, which after quality control summed up to ~ 3,5 billion sequences. After assembly we obtained 1,284,307 scaffolds with an average N50 value among the samples of 3662 bp. The longest scaffold was 596,794 bp, which corresponds to half a genome of a small genome-sized free-living prokaryote. In addition, we generated 313,855 16S and 176,566 18S amplicon sequences to further explore the effects of TCS on community structure, and to compare shotgun and amplicon sequencing approaches. Bioinformatic analyses are ongoing, but first annotation results using TIGRFAM identified genes from 3415 functional classes, of which 656 were differentially abundant in unexposed control communities vs. communities exposed to 316 nM TCS. The composition of these protein-encoding gene families in control communities and communities exposed to 316 nM TCS was cleary different. TIGRFAMS that were found to be significantly more abundant in exposed communities included, for example, those for protein and energy metabolism, metal resistance and various transporters (including ABC-transporters). TIGRFAMs significantly more abundant in unexposed controls included, for example, many genes encoding photosynthesis proteins. We will also present further analyses of TCS effects on functional and taxonomic composition, as well as analyses of proteins correlated to TCS tolerance. To our knowledge, this is the first large-scale metagenomics study of toxicant effects on microbial commuities.

Human activities can cause soil metal pollutions and therefore modify soil ecosystem functioning. Eucaryotic microorganisms are an important element in ecosystems: for example, the eukaryotic predators regulate bacterial populations by grazing them. If a metal pollution occurrs, organisms have to provide resistance mechanisms to prevent toxic effects on cell components, like DNA damage or metabolism disturbance. For this purpose, intracellular chelation is an important mechanism enabling organisms to limit metal toxic effects by synthesis of metal binding molecules with a high cysteine content such as metallothioneins (MTs). MTs are a superfamily of low molecular weight proteins rich in Cys (15-33%), divided into 15 different families depending on their amino acid sequence features. They have a physiological dual role: metal homeostasis in physiological conditions and protector in response to metal excess. Here, by a functional metatranscriptomic approach, we isolated for the first time eukaryotic environmental metallothioneins (EMTs). Their DNA sequences were recovered by specific PCR in diverse soil samples revealing that the organism(s) bearing these genes is(are) ubiquitous. We have characterized EMTs with respect to their amino acid sequence features and to their metal binding abilities (studied by ESI-TOF-MS after protein overexpression in *E.coli* in the presence of Zn, Cd or Cu and subsequent purification of the respective metal complexes). EMT sequences present particular properties that strongly relate them to typical MTs: a high content of conserved Cys residues (20-24%), Cys residues mainly distributed in specific sequential motives (1 CCC, 2 CXCC, 2-3 XCCX, and 4 CXC), and no aromatic amino acids. But they have unusual features too: an “important” length (110-132), the presence of CCC clusters, two conserved His residues and a cysteine-free sequence linker dividing the protein sequence in two parts. After purification of the corresponding metal complexes, ESI-TOF-MS analysis revealed that EMT proteins are able to bind Cd, Zn and Cu, likewise the MT proteins. In most of the cases : i) some mixtures of metal-protein species, ii) the presence of sulphide ligands in the Cd-EMT complexes, and the presence of heteronuclear Zn,Cu-EMT species, as the result of the Cu-supplemented syntheses, were observed suggesting that EMTs have no specific metal binding preferences. These data reveal that EMTs define a new metallothionein family.

DYMICO, metaproteomic analysis of environmental microbiome dynamics as response to pollutants and stressors

J. Kuruvilla, Linköping University / Clinical and Experiemental Medicine; G. Danielsson, Stockholm University / Biochemistry and Biophysics; S. Cristobal, Linköping University / Department of Cl and Exp Medicine Cell Biology

Metaproteomic analysis could provide a functional overview from several level of complexity: at the community level, how the communities respond to the exposure or stress; at the molecular level, which protein families have been modified their level of expression; and at the biochemical level, which catalytic reaction with relevant role to maintain the community in equilibrium. We presented the metaproteomic analysis of aquatic sediments from Baltic Sea exposure to propranolol and salinity changes for 6 weeks. We tested if a metaproteomics-based assessment can estimate: i) variation in the abundance of protein families, ii) changes in biodiversity, and iii) what are the key players in the community that drive the variation in the community and the adaptation to the exposure to pollution and to abiotic changes in the environment. The SDS-boil method for protein extraction has increased the amount of protein recovered as well as the biodiversity. This method was offering the highest values for reproducibility among biological replicates. Our results indicate that two step in the data analysis pipeline are crucial to implement this methodology for environmental assessment: the selection of the database or the utilization of an in-house database for protein identification, and the comparison between search engines. We compare our results from two database: Cameraand NCBI non-redundant repository database and the LC-MS (2)-spectra were searched using a combination of two different search engines: Unipept or MEGAN against different database. The salinity stressor has an important impact into the community response. Our results indicated the analysis of microbial community dynamics could be correlated to both changes in the molecular responses of the communities, interspecies interaction and therefore interprete and predict the ecosystem response to stressors or exposure to pollutants. Furthermore, we can explore the prediction capabilities of these methodologies to develop a metaproteomics-based environmental assessment.

Pollutant risks to amphibians and reptiles: how much we know and what we need

Compared ecotoxicity of raw and oxidised carbon-based nanoparticles on Xenopus laevis larvae

L. Lagier, S. Cadarsi, ECOLAB UMR5245 CNRS UPS INPT; A. Mottier, ECOLAB UMR5245 CNRS; C. SARRIEU, E. Flahaut, CIRIMAT UMR CNRS 5085 UPS INPT; E. Pinelli, F. Mouchet, L. GAUTHIER, ECOLAB UMR5245 CNRS UPS INPT

Carbon-based nanoparticles (CNPs) such as carbon nanotubes or graphene have numerous attractive properties leaching to their use in many application fields whether they are raw or functionalised, such as oxidised. More and more produced, these nanoparticles may finally contaminate the aquatic environment, which is a major receptacle of pollutants. This work consists in assessing the ecotoxicological risks induced by a range (from 0.05 to 50 mg.L-1) of double-walled carbon nanotubes (DWCNTs) and few layer graphene (FLG) on the amphibian *Xenopus laevis*. We studied the influence of surface chemistry by comparing raw materials with their functionalised counterparts by testing different oxidation levels and thus different nanoparticles: oxidised DWCNTs

(DWCNTs-ox), graphene oxide (GO), and reduced graphene oxide containing respectively 4 and 17 % (atomic composition) of oxygen (rGO 4%, rGO 17%). Tests have been carried out with a standardised protocole (ISO, 2006). We focused on various endpoints: (i) mortality, (ii) growth inhibition and (iii) genotoxicity (induction of micronucleated erythrocytes). The mortality was not significantly impacted whatever the type of nanoparticle and tested concentration. In contrast, a significant growth inhibition was observed from 10 $mg.L^{-1}$ of raw DWCNTs and FLG, and at 50 $mg.L^{-1}$ of DWCNTs-ox and GO. On the contrary, growth significantly increased for larvae exposed to 1 $mg.L^{-1}$ of rGO 4% and rGO 17% comparatively to the negative control. No genotoxicity was noted for the raw nanomaterials nor for rGO 4 and 17 %, but significant genotoxicity was observed for DWCNTs-ox at 1 $mg.L^{-1}$ and for GO at 0.1 $mg.L^{-1}$. The chronic toxicity observed appeared to be limited to physical effects (intestinal obstruction and/or abrasive effects and/or nutrients deprivation and/or gill clogging). However, genotoxic effect could be attributed to intrinsic properties of oxidised nanoparticles. This work has been carried out in the framework of the Graphene Flagship program. Key words: carbon-based nanoparticules, oxidation, ecotoxicity, *Xenopus laevis* References ISO 21427-1. International Standard. Water quality - Evaluation of genotoxicity by measurement of the induction of micronuclei - Part 1: Evaluation of genotoxicity using amphibian larvae. ISO 21427-1, ICS: 13.060.70, Genova – CH (2006). Effects of a glyphosate-based herbicide and temperature on the development of Common toads (Bufo bufo, L.; Amphibia: Anura)

F. Baier, E. Gruber, University of Natural Resources and Life Sciences Vienna / Institute of Zoology; B. Spangl, University of Natural Resources and Life Sciences Vienna / Institute of Applied Statistics and Computing; J.G. Zaller, University of Natural Resources and Life Sciences Vienna / Institute of Zoology

Herbicides based on the active ingredient glyphosate are increasingly applied in agriculture, horticulture and private gardens all over the world. Recently, leaching of glyphosate or its metabolite into water bodies inhabited by amphibians has been reported. However, very little is known about non-target effects of these herbicides on amphibians and even less is known to what extent different temperatures might alter these effects. Using climate chambers, we investigated the effects of the glyphosate-based herbicide Roundup PowerFlex® (480 g L^{-1} glyphosate, formulated as 588 g L^{-1} potassium salt) on the larval development of Common toads (*Bufo bufo*, L.; Amphibia: Anura) under different temperature regimes (15°C vs. 20°C). We established five herbicide concentrations: 0, 1.5, 3, 4 mg acid equivalent L^{-1} and a 4 mg a.e. L^{-1} pulse treatment (totally three applications of 1.5, 1.5 and another 1 mg a.e. $L^{-}1$) at each temperature in a full-factorial design. Each treatment combination was replicated 5 times; the experiment ran for 24 days. Results showed no effect of herbicide concentration on body length and body width but a highly significant effect of temperature on these growth parameters. Moreover, highly significant interactions between herbicide and temperature on body length and body width were observed suggesting that herbicides had different effects on different temperatures. \n In conclusion, although Roundup PowerFlex® at the tested concentrations appeared to have no acute toxicity to larvae of Common toads, the observed effects on tadpole growth will potentially affect competitive interactions in spawning ponds of amphibians. Our findings of herbicide x temperature interactions might become more prevalent when human-induced climate change will lead to more extreme temperatures.

Standardize or diversify conditions in experimental ecotoxicology? A case study on herbicide toxicity to larvae of two anuran amphibians

Z. Mikó; J. Ujszegi, Hungarian Academy of Sciences / Lendület Evolutionary Ecology Research Group; Z. Gál, Agricultural Biotechnology Institute / NARIC; A. Hettyey, Hungarian Academy of Sciences / Lendület Evolutionary Ecology Research Group

As part of the biodiversity crisis, amphibian species are experiencing population declines and extinctions throughout the world. One of the major causes of these declines is increasing pesticide use. Even though there is a steeply increasing number of ecotoxicological studies treating the effects of pesticides on non-target organisms, studies assessing the adequacy of different experimental approaches have remained scarce. We scrutinized effects of a glyphosate-based herbicide on larvae of two European anuran amphibians by estimating species-specific LC50 values. To assess how an additional factor may influence outcomes of a standard toxicity test, we investigated whether predation threat exacerbated the effects of the pesticide. Finally, to study how repeatable the measured effects are across experiments, we performed experiments repeatedly. We exposed agile frog (Rana dalmatina) and common toad (Bufo bufo) tadpoles to two predator treatments (no predator, dragonfly larvae) combined with seven (0, 0.009, 0.03, 0.24, 1, 2, 6.5 mg a.e. / L glyphosate) and nine (0, 1, 2, 3, 4, 5, 6, 7, 8 mg a.e. / L glyphosate) herbicide concentrations in a full factorial design and repeated the experiment with a subset of the experimental treatments and partly with slight modifications one week later on another set of animals. Our results indicated that the herbicide was moderately toxic to the studied animals. The presence of chemical cues on predation threat increased the toxicity of the herbicide in case of agile frog tadpoles, but, surprisingly, made the herbicide less lethal for common toad tadpoles. The repeatability of the experimental results across experiments differed between the two species: the estimated sensitivity of agile frog tadpoles varied considerably, while in case of the common toad LC50 values remained very similar across experiments. Our results support the hypothesis that the effects of pesticides can be significantly influenced by additional stress factors and by slight changes in the experimental setup, all also depending on the studied species. This draws attention to the suggestion that strict standardization may not deliver widely applicable insights into the toxicity of contaminants and, instead, introducing some variation into the design of future ecotoxicological experiments may prove highly beneficial.

New histological and molecular biomarkers for developmental reproductive toxicity in Xenopus tropicalis

M. Säfholm, E. Jansson, Uppsala University / Dept of Environmental Toxicology; C. Berg, Dept. of Environmental Toxicology / Dept of Environmental Toxicology

The risk posed by plant protection chemicals to amphibians shall be evaluated according to the EU Plant Protection Product Regulation. To accomplish this, amphibian test methods for investigating adverse effects of chemicals need to be developed. The present study aimed to develop the *Xenopus tropicalis* test system for developmental reproductive toxicitybycharacterising molecular and histological features of sexual development**.** The ontogenetic development of the Müllerian ducts (precursors of the female reproductive tract) was characterized histologically. In addition, the mRNA expression of *amh* (*anti-Müllerian hormone*), *amhr2* (*amh receptor 2*),*intracellular and membrane progesterone receptors* (*ipgr* and *mpgr beta*) and *cytochrome P450 19a1* (*cyp19a1)* were determined in the urogenital complex (composed of kidney tissue, gonads and sex ducts). *amh* expression was evaluated as a molecular biomarker for phenotypic sex.The animals were sampled for mRNA analysis duringsex differentiation at Nieuwkoop and Faber (NF) stage 51 and 56, and at 4 weeks post-metamorphosis. Gonadal and Müllerian duct development were characterized histologicallyat 4 weeks post-metamorphosis. As *X. tropicalis* displays a high variability in larval developmental rate, the sampling scheme was designed to obtain both age- and stage matched groups.The results show that the *amh* mRNA expression levels were higher in individuals with low *cyp19a1* expression (ovarian marker) and vice versa. The sexually dimorphic expression profile was more distinct for *amh* than for *cyp19a1*, supporting our hypothesis that *amh* expression is useful as a testicular biomarker during gonadal differentiation in *X. tropicalis*.The *pgrs* expression levels increased over the studied period and showed no sex differences. The*amhr2* expression level was higher in females than in males at NF 56 and at 4 weeks post-metamorphosis. The histological evaluation showed that folliculogenesis had initiated and that the Müllerian ducts were larger in females than in males. The proportion of follicular oocytes in the ovary at 4 weeks post-metamorphosis increased with increasing time for the individual to complete metamorphosis, emphasizing the importance of having study groups that are both age- and stage matched in toxicity studies of larval amphibians. This new knowledge on sexual development in *X. tropicalis* is useful in the development of early life-stage endpoints for developmental reproductive toxicity.

452

Acute oral toxicity in terrestrial life stages of amphibians: comparisons to birds and mammals

L. Weltje, BASF SE / Crop Protection Ecotoxicology; M. Crane, AG-HERA; M.C. Finnegan, Syngenta; S. Kosmala-Grzechnik, M. Gross, WCA Environment; J. Wheeler, Dow Agrosciences

Amphibians are currently the most threatened and rapidly declining group of vertebrates and this has raised concerns about their potential sensitivity and exposure to plant protection products and other chemicals. Current environmental risk assessment procedures rely on surrogate species (e.g. fish and birds) to cover the risk to aquatic and terrestrial life stages of amphibians, respectively. Whilst a recent meta-analysis has shown that in most cases amphibian aquatic life stages are less sensitive to chemicals than fish, little research has been conducted on the comparative sensitivity of terrestrial amphibian life stages. Therefore, in this paper we address the questions “What is the relative sensitivity of terrestrialamphibian life stages to acute chemical oral exposure when compared with mammals and birds?” and “Are there correlations between oral toxicity data for amphibians and data for mammals or birds?”. Identifying a relation between these data may help to avoid additional vertebrate testing. Acute lethal oral amphibian toxicity data collected from the scientific literature and ecotoxicological databases were compared with toxicity data for mammals and birds. It was found that toxicity data for terrestrial amphibian life stages are generally sparse, as noted in previous reviews. However, the single-dose oral toxicity data for terrestrial amphibian life stages that are available for 23 chemicals suggest that oral toxicity to terrestrial amphibian life stages is similar to or lower than that for mammals and birds, with a few exceptions. Thus, mammals or birds are considered adequate toxicity surrogates for use in the assessment of the oral exposure route in amphibians.

453

Do developmental stage and route of exposure determine pesticide effects on lizards?

I. Trajcheska, University of Koblenz-Landau / Institute for Environmental Sciences; M. Ortiz Santaliestra, Institute for Environmental Sciences University of Koblenz-Landau / Institute for Environmental Sciences; L. Delaporte, University of Koblenz-Landau / Institute for Environmental Sciences; C. Bruehl, University of Landau, Institute for Environmental Sciences / Institute for Environmental Sciences

Reptiles are an understudied group in ecotoxicology and the risk of pesticides on them is supposed to be covered by bird and mammal toxicity data derived from oral exposures. However, topic exposure during egg incubation, as well as dermal uptake and/or overspray of pesticides once hatchlings leave the nest could constitute relevant exposure ways for reptiles. We conducted a two-stage exposure of wall lizard (*Podarcis muralis*) eggs and hatchlings to three pesticides in order to analyse the effects of pesticide exposure on each developmental stage and to compare the relative importance of dermal and oral exposure of juveniles through different exposure routes. Eggs were incubated in soils previously sprayed with a pesticide solution corresponding to 40% of the field application rate (to consider relevant crop interception) of formulations of either glufosinate ammonium (herbicide), folpet (fungicide) or fenpyroximate (insecticide). Eggs exposed to folpet hatched earlier and with a lower body mass than controls, whereas fenpyroximate reduced body size at hatching. Upon hacthing, animals were assigned to a juvenile treatment consisting in the exposure through spiked soil (dermal) or food (oral) in a factorial block design considering both in-ovo and hatchling exposure. Concentrations during the hacthling exposure corresponded to 25% of the application rate. Interestingly, egg exposure but not hatching exposure determined the body mass gain during the post-hatch stage of lizards exposed to glufosinate ammonium or fenpyroximate. Oxidative stress biomarkers showed different trends as a function of life stage; the activity of glutathione peroxidase was increased after egg exposure to folpet and glufosinate ammonium and also after juvenile exposure to any pesticide. However, in animals exposed to folpet as eggs, further exposure to the fungicide as juveniles reduced the activity of the enzyme, which could be interpreted as a hormetic response consequence of a saturation of the enzyme synthesis under prolonged exposures to folpet. Effects of pesticides on juveniles exposed either dermally or orally were very similar, which suggests the conenience of considering dermal exposure in risk assessment for reptiles as an additional route of pesticide uptake. In addition, our result highlight the importance of considering lagged effects in pesticide risk assessment. Financed by the EU's FP7 (IEF-2012-328328)

Are we going about chemicals risk assessment for the aquatic environment the wrong way?

454

Assessing risks and regulating the many 1000s of man-made chemicals how can we cope?

J.P. Sumpter, Brunel University / Institute of Environment Health and Societies

Tens of thousands of man-made chemicals are in everyday use in developed countries. A high proportion of these, or their transformation products, probably reach the aquatic environment. A considerable amount is known about the environmental concentrations of some of these chemicals (such as metals), especially the regulated ones, but little or nothing is known about the majority. In densely populated countries, most or all rivers will receive both diffuse (e.g. agricultural runoff) and point source (e.g. sewage treatment plant effluent) inputs, and hence be contaminated with complex, ill-defined mixtures of chemicals. Most freshwater organisms will be exposed, to varying degrees, to this contamination. The number of species exposed is in the thousands, and quite possibly tens of thousands. Little is known about whether or not these species are adversely affected by the chemicals present in their environment. Often it is not even known what species are present, let alone whether they are affected by the chemicals present. In a few high-profile cases (e.g. tributyl tin causing imposex in molluscs and oestrogens 'feminizing' male fish), chemicals have undoubtedly adversely affected aquatic species, occasionally leading to population crashes. Whether or not other chemicals are affecting less visible species (such as most invertebrates) is largely unknown. It is possible that only very few chemicals in the freshwater environment are adversely affecting wildlife, but it is equally possible that some effects of chemicals are, as yet, undiscovered (and may remain so). Nor it is clear which chemicals may pose the greatest risk to aquatic organisms. All these uncertainties leave much to chance, yet designing a regulatory system that would better protect aquatic organisms from chemicals is difficult. A more flexible and intelligent strategy may improve the current situation. Finally, the risk due to chemicals is put into context with the many other threats, such as alien species and new diseases that undoubtedly can pose significant risks to aquatic ecosystems.

455

The prioritisation of substances and the derivation of Environmental Quality Standards under the Water Framework Directive - how did we get to where we are?

D. Leverett, WCA-Environment Ltd

The WFD aims to provide a holistic approach to managing the water environment in Europe, and brings together objectives to protect the water environment from the effects of chemical pollution and broader ecological objectives, designed to protect the structure and function of aquatic ecosystems themselves. Under the WFD, the overall environmental status of a waterbody (be it river, lake, estuary or coastal) is determined by the assessment of its ecological and chemical status. Chemical status is based on the comparison of the measured concentrations of 'Priority Substances' with their substance-specific Environmental Quality Standard (EQS), which represents the concentration below which effects on populations of organisms are not expected to occur. The list of 'Priority Substances' regulated under the WFD is updated on a 4-5 year cycle, and currently comprises around 40 substances or groups of substances. While this set of substances is considered (at least under the auspices of the WFD) to represent those with the potential to cause the greatest harm to the environment, it clearly does not comprise all substances with demonstrated adverse effects on aquatic organisms nor even all such substances that have been detected as being present in European waters. How then have we ended up with this particular set of substances? The first part of this presentation will therefore outline and review the approaches and procedures that have been, and are currently, used to identify and prioritise candidate substances for potential regulation under the WFD. Once candidate substances have been identified and prioritised as candidates, the next stage in the review process is to compile and evaluate as much existing information on each candidate substance as possible, in order to undertake a preliminary risk assessment. At this stage, all data on the potential effects of a substance are subject to in-depth scrutiny and this usually generates much debate (and often disagreement) amongst those responsible for deriving the concentration deemed 'safe' for the environment. This debate generally focuses on the quantity and quality of the underlying ecotoxicity studies, and specifically the reliability and relevant of certain studies (usually those that have generated effect thresholds at the lowest concentrations, and on the magnitude of assessment factors applied to such thresholds in order to account for the uncertainties inherent in the assessment. The second part of this presentation will therefore deal with the techniques used to derive Predicted No Effect Values (PNECs; the precursors to EQS), the types of ecotoxicological data considered relevant in predicting population-level effects, the quantity of data required, the approaches used to assess the reliability of the underlying data, the uncertainties in the process, and the use of assessment or safety factors in deriving EQS. In this part of the presentation, we will also address the criteria for the assessment of persistent, bioaccumulative and toxic substances (PBT), and how the outcomes of the PBT assessment affect the future regulation of substances. While considerable scrutiny is placed on such effects data, the data on measured concentrations in the environment generally receives much less focussed attention (both at the prioritisation and preliminary risk assessment stages). Exposure data is often derived from only a very small, and largely unrepresentative, series of monitoring points in European waters, and is generally not subject to the type of in-depth reliability and relevance assessments applied to effects data. Nevertheless, such data is critical in the prioritisation process, and a lack of quantity and/or quality in exposure data has at least an equal effect (and debatably more so) on the outcomes of the process as the ecotoxicological effects information. Therefore, the final part of this presentation will cover the identification and evaluation of exposure data, and measures to improve this element of the overall assessment, including the WFD Watch List.

456

Does the current risk assessment of chemicals underestimate toxic stress in Europe?

P. Von der Ohe, UBA - Federal Environment Agency / IV Pharmaceuticals

There is evidence that anthropogenic chemicals can have profound local and regional effects on aquatic communities, while the overall relevance of chemicals regarding larger spatial scales remains mostly unknown. The reason for this are both the lack of comprehensive monitoring datasets as well as the availability of respective ecotox-data. Here we present the first risk assessment of organic chemicals on a continental scale. The study is based on regulatory monitoring data for a total of 4,000 monitoring sites available from the European Environmental Agency for the years 2008-2012. For the 223 organic substances monitored, the available experimental ecotox-data was collated and supplemented by QSAR predictions in case of data gaps. Results showed that organic chemicals are likely to exert acute lethal and chronic long-term effects on sensitive fish, invertebrate, or algae species in 14 % and 42 % of the sites, respectively. Pesticides, brominated flame retardants, and tributyltin were the major contributors to the overall chemical risk. Their presence was related to agricultural and urban areas in the upstream catchment. Moreover, the risk of potential acute lethal and chronic long-term effects increased with the number of eco-toxicologically relevant chemicals that have been analyzed at each site. However, as most monitoring programs considered in this study often included only a subset of these chemicals, our assessment is likely to underestimate the actual risk. \n Finally, we analyzed whether the observed chemical concentrations had any effects on aquatic communities. For that reason, we used a sub-set of sites in France where many of these relevant chemicals have been analyzed and concurrent community data was available. We found that an increasing chemical risk was associated with increased deterioration in water quality indices for fish and invertebrates communities. Our results therefore clearly indicate that chemical pollution is a large-scale environmental problem that requires far-reaching, holistic mitigation measures to preserve and restore ecosystem health. It also suggests that current risk assessment approaches on a substance by substance bases are likely not protective for the environment. This is especially so when considering that the large and chemically diverse group of pharmaceuticals has not been included in this study, due to a lack of monitoring data as well as appropriate ecotox data that considers the specific effects of these substances in wildlife. Examples for the latter include the feminization of the male roach (*Rutilus rutilus*), a widespread group-spawning fish in English rivers, due to water-borne estrogens, or the population decline of the oriental white-backed vulture (OWBV; *Gyps bengalensis*), which was associated with renal failure and visceral gout after feeding on prey treated with anti-inflammatory drugs.

457
Forwarding sustainable use of chemicals via ecological impact analyses: the eco-epidemiological approach
D. DeZwart, DdZ-Ecotox; S.D. Dyer, The Procter & Gamble Company / Environmental Stewardship and Sustainability Organization; M. Huijbregts, Radboud University Nijmegen / Department of Environmental Science; A.M. Schipper; A. Pilière; K.E. Kapo, C.M. Holmes, Waterborne Environmental, Inc.; A. Burton, University of Michigan / School of Natural Resources   Environment; L. Posthuma, RIVM / Centre for Sustainability Environment and Health
Monitoring data have delivered us only fragmented insights in chemical exposures of biota (man and species in ecosystems) and – in fact – very little insights in net impacts. With approx. 80-100k chemicals produced regularly by man, exposing millions of species, the question is whether we are on the right track in the scientific enterprises underpinning chemical safety regulations. The tome '*Chemicals without harm'* (Geiser, 2015, reviewed in *Science*, DOI 10.1126/science.aac9931) collates some visionary approaches towards a safe and sustainable chemical economy. Prioritizing the design of novel chemicals and products being a key step. But logically, we also need to fill the gap between the low percentage of chemicals being considered by regulations and the plethora of chemicals and mixtures out there. Eco-epidemiological analyses have been proposed already in 1984 to diagnose impacts of chemicals and their mixtures in ecosystems. It is only in the last decade that this diagnostic approach has gained further attention, enabled by the large growth of monitoring data as well as analytical modelling power. This contribution describes the eco-epidemiological approach and how preventive regulatory action on various chemical groups together with field impact assessments have brought the field forward. The approach starts by ranking sites where ecological impacts are highest and where this is likely to be attributable to chemical mixtures, then in ranking contributions of specific chemical(s) (groups) in those effects. This enables a solution-focused approach to abatement to be chosen. Examples are presented from a decade of eco-epidemiological diagnostic analyses, in the context of solution-focused approach to forward the sustainable use of chemicals.

458
Does evidence from field population studies of aquatic wildlife suggest laboratory ecotoxicology information is misleading?
A. Johnson, CEH Wallingford / Wallingford
With endocrine disruption the evidence from aquarium tests together with the inspection of wild fish anatomy pointed to a threat to fish populations living in proximity to sewage effluents. This issue has in part led the EU for the first time to put three 'pharmaceuticals', ethinylestradiol, estradiol and diclofenac, on a watch list potentially leading to them being priority substances needing control. Despite these concerns and enthusiasm for control, we still don't know if fish populations are actually being harmed by pharmaceuticals or estrogens in sewage (wastewater) effluent. It is important to distinguish here between harm to individuals (for which evidence certainly exists for estrogens) and harm to populations. Harm to individuals is a matter of regret, whilst harm to populations is a potential catastrophe. Recent evidence implies that we may not be facing a disaster. Compilation of fish catch data caught for recreation in the UK has been on an upward trend since the 1970s. We have recently compared the abundance of wild fish populations in the UK with wastewater exposure and over the past 10 years and there was no relationship. Looking at annual trends in abundance of different fish species has not shown declines in response to years of high wastewater exposure. In some cases roach (Rutilis rutilis) populations have grown in response to years of higher effluent exposure. Similarly, macroinvertebrate families do not seem to behave as we expect. Thus, whilst diversity is reduced with wastewater exposure, the trends in individual families are not so predictable. Thus, population abundance can grow in years were high wastewater exposure occured. The prevalence of sensitive families was not linked to levels of wastewater exposure. Nevertheless, some would argue that the precautionary principle requires us to act where a concern exists, even though the evidence may be insubstantial. However, governments still require some calculation of proportionality to be carried out. In other words, are the costs of a remedy proportional to the threat? This puts regulators in a dilemma, since the key evidence of harm to fish populations is lacking. Scientists are not the decision makers and regulators may still proceed on the evidence of harm to individual wildlife. But evidence on the state of populations in response to the challenge of chemicals in effluent still remains a great unknown in the debate.

Consensus building in life cycle impact assessment: experiences, achievements and challenges

460
General description and introduction
R. Frischknecht, treeze Ltd.
Improving life cycle impact assessment models to be applied in the integrated environmental assessment of products is crucial. Several efforts are ongoing to address this need of improvement. To answer this, the UNEP---SETAC Life Cycle Initiative (2012---2017) has launched a flagship project to provide global guidance and build consensus on environmental LCIA indicators (see http://www.lifecycleinitiative.org/). The flagship project is focusing on building Improving life cycle impact assessment models to be applied in the integrated environmental assessment of products is crucial. Several efforts are ongoing to address this need of improvement. To answer this, the UNEP-SETAC Life Cycle Initiative (2012–2017) has launched a flagship project to provide global guidance and build consensus on environmental LCIA indicators (see http://www.lifecycleinitiative.org/). The flagship project is focusing on building consensus for different impact categories. A Pellston workshop (to be held in January 2016) will be devoted to find consensus on a first set of impact categories, namely: land use impact on biodiversity, water depletion, respiratory inorganics, climate change. The overall LCIA framework as well as several cross cutting issues will be also discussed. A common case study is being developed and serves to test and evaluate the harmonised impact indicators and to ensure their practicality. The aim of the special session is to report the result of the Pellston workshop and to discuss the way forward, e.g. in policy and business related contexts. Regarding the European policy context, the European Commission is aiming at a similar process covering land use related impact at midpoint, water related impact, respiratory inorganics and resource depletion to be used in the context of the Product Environmental Footprint (PEF) studies. Progress on this impact assessment harmonization process will also be presented in this session. Acceptability and applicability of the methods will be discussed aiming at improving the use of the methods in practice and the interpretation of the results. The session will also place some emphasis on the balance between continued methodological development and the need for stability and consensus for more efficient use of life cycle approaches in policy and private sector, supporting decision-making and communication.

461
The WULCA consensus for water scarcity footprints: Assessing impacts of water consumption based on human and ecosystem demands
A. Boulay, CIRAIG - École Polytechnique de Montréal / Chemical engineering department
The need for consensus-developed and recommended methods for water use impact assessment is clear in order to perform a water scarcity footprint consistently with ISO 14046:2014 and for consistently assessing water consumption impacts in LCA. This challenge was undertaken by the WULCA working group, of the UNEP-SETAC Life Cycle Initiative in 2013. Including method developers and experts from different fields, the group developed a consensus-based indicator to assess impacts from water consumption at the midpoint level, complying with the requirements of the ISO document. This work presents the recommended methodology for performing a water scarcity footprint including a case study application. The process started with the identification of the question to answer and three proposals which emerged from the three expert workshops held in Zurich, San Francisco and Tsukuba in 2014. The group then selected criteria used to evaluate the proposals which led to a preliminary recommendation presented in 2015. From this recommendation and the testing phase that followed, additional specific and influential modeling choices were identified, analyzed and adjusted accordingly, and sensitivity analysis were performed on the most uncertain aspects. These choices and analysis are presented, which include the span of the indicator, the different choices of spatio-temporal aggregation and their meaning when the native resolution of the indicator cannot be used, and the sensitivity of the environmental water requirement (EWR) parameter. The resulting and consensus-based single metric, covering the entire globe, modelled at various temporal and spatial scales for application in LCA, is presented in details along with the interpretation and application on the rice case study. The group is proposing the result of its work and new consensus-based indicator with the expectation that it will be adopted widely and hence decrease disparity and confusion when it comes to applying the new ISO standard on water footprinting, by providing an internationally approved,

robust and simple indicator for assessment of potential impacts from water consumption.

462
Characterisation of water scarcity impact on human health – development of a consensus-based model within WULCA
M. MOTOSHITA, National Institute of Advanced Industrial Sci. and
Human health is one of the impacted area of protection from water scarcity. There are several characterisation models to assess the impacts on human health caused by agricultural/domestic water scarcity. However, these models characterise the impacts on human health in different ways even though they focus on the same impact pathways. A recommended characterisation model has been developed based on consensus among method developers and stakeholders in WULCA working group of UNEP/SETAC Life Cycle Initiative. As a first step for the development, sensitivity of parameters used in effect factors of previously developed models on agricultural water scarcity (Pfister et al. 2009; Boulay et al. 2011: Motoshita et al. 2014) and domestic water scarcity (Motoshita et al. 2011; Boulay et al. 2011) were analysed and reviewed to identify critical parameters in characterisation model. The results of sensitivity analysis indicated the significance of health response factor to food/household water deficit and adaptation capacity to potential health damage. In order to test the validity of different types of health response factors and adaptation capacity, health damage due to agricultural/household water deficit was estimated based on those factors and compared with malnutrition/diarrhoea damage reported by WHO. According to the comparison of estimated and reported damage, health damage per calorie/water in deficit and inequality adjusted adaptation capacity (HDI-base) showed closer estimation of health damage to WHO report. Regarding agricultural water scarcity, food trade effects also showed high influence on the effect factor. The trade effect factor is composed of food supply dependency on domestic and imported food, as well as of the adaptation capacity through trade. Critical parameters of trade effect are identified through sensitivity analysis. The outcome of these discussions and the rice case study allowed the group to build a recommended methodology integrating the optimal options for each of these modelling choices. This recommended model is presented as an output of this consensus building within the UNEP/SETAC LCI flagship project of environmental life cycle impact assessment indicators and we expect it to improve the results of water consumption impacts in LCA and water footprinting.

463
Biodiversity impacts of land use
A. Assumpcio, IRTA; L. Mila i Canals, UNEP
Land use and land use change are main drivers for biodiversity loss and degradation of a broad range of ecosystem services. Despite substantial contributions to address biodiversity in LCA, no clear consensus exists on the use of specific impact indicator(s) to quantify land use impacts on biodiversity. This lack of consensus not only limits the application of existing models, but also imposes constraints on the comparability of results of different studies evaluating land use impacts based on applying different models. This TF aims at global guidance and consensus regarding indicators and methods for the assessment of biodiversity impacts from land use in LCA. In order to identify models of particular promise for further application and development, Land use Task force has performed a review of existing indicators in and out of the field of LCA. 30 models were selected. Based on the approach used by the European Commission within the International Reference Life Cycle Data System, we grouped sets of evaluation criteria under the following categories: completeness of scope; biodiversity representation; impact pathway coverage; scientific quality; model transparency and applicability; and stakeholder acceptance. In addition, two expert workshops were organized during 2014 (San Francisco, USA, 7/11 and Brussels, BE, 18-19/11). The events included discussions centred on four key topics: (a) concept of biodiversity and modelling strategies, (b) data availability and feasibility, (c) desired characteristics of indicators, usability and consensus and (d) concerns and limitations about using biodiversity indicators in LCA. Based on outcome of expert workshops and revision conducted we could summarize that there is clearly a need to model characterisation factors in terms of both (i) local damage factor for direct land use, and (ii) regional "state and pressure" weight to reflect broader biodiversity patterns and processes surrounding the location of land use. For reasons of data availability, species richness is an obvious candidate for both local, and regional damage. However, species richness is insufficient to depict the complexity of biodiversity and ecological processes. One pragmatic way of building consensus would be to use a combination of available indicators from the reviewed models for both local and regional biodiversity damage. A rice case study is developed to test different options.

464
Health effects from indoor and outdoor exposure to fine particulate matter in life cycle impact assessment
T.E. McKone, University of California / School of Public Health; P. Fantke, Technical University of Denmark / Quantitative Sustainability Assessment Division
Fine particulate matter (PM2.5) pollution has been estimated to contribute more than 7% to the total global human disease burden from 1990 to 2013 (http://healthdata.org/gbd). Ambient (outdoor) and household indoor PM2.5 exposures are reported to account for 41% and 58% of this impact, respectively, emphasizing the need to include both, outdoor and indoor exposure into overall estimates of health burdens in life cycle impact assessment. However, lacking clear guidance on how to consistently include health effects from exposure to PM2.5 in life cycle perspective, practitioners fail to report related life cycle impacts. To address this gap, a global initiative has worked on building a coupled indoor-outdoor intake fraction framework combining exposure to PM2.5 emitted indoors and outdoors with exposure to PM2.5 formed indoors and outdoors from chemical reactions. An exposure-response model derived from ambient PM2.5 concentrations is consistently combined with exposures from indoor and outdoor sources. All factors are systematically built into a model parameterized for different archetypal outdoor and indoor settings, such as specific residential and occupational settings and different urban area sizes. Model and parameters are tested in a case study on the production and processing of rice in three distinct scenarios covering urban China, rural India and U.S.-Europe. Recommendations are to use this coupled, generic framework whenever emission locations are unknown and to apply spatial models whenever emission locations are known. Our study constitutes a first step towards providing guidance on how to include health effects from PM2.5 indoor air exposures in product-oriented impact assessments.

465
Improving global warming impact assessment: From recent developments in climate science to LCA practice
A. Levasseur, CIRAIG - École Polytechnique de Montréal / Chemical Engineering; F. Cherubini, NTNU / Energy and Process Engineering
In life cycle assessment (LCA), global warming impacts are usually assessed using Global Warming Potentials (GWP) for a 100-year time horizon as published by the Intergovernmental Panel on Climate Change (IPCC). In the recent past years, concerns have been raised regarding the use of appropriate modeling choices and alternative metrics have been proposed. The Global Warming Task Force of the project entitled Global Guidance on Environmental LCIA Indicators let by the UNEP/SETAC Life Cycle Initiative has performed an extensive critical review of current knowledge and limitations regarding climate metrics. Topics such as the consideration of near-term climate forcers, the inclusion of carbon-cycle and climate feedbacks in GWP, or the consideration of biogeophysical climate forcings from land use and land cover changes have been discussed. Special focus has been set toward new findings presented in the fifth IPCC assessment report, Working Group I, Chapter 8. The pros and cons of each modeling choices have been identified and recommendations have been drafted. The main line of thought is to first use more than one indicator (e.g. different time horizons, with and without carbon-cycle and climate feedbacks) to test the sensitivity of global warming LCA results to the different metric choices. If conclusions are unchanged, LCA results are robust. If they change from one metric to another, the range of results should be used to communicate about the sensitivity of LCA results to the metric choice. Metrics using different modeling choices have then been applied to a case study about the consumption of rice in three regions of the world. It has shown that LCA results may be particularly sensitive to the time horizon selected, and that the consideration of near-term climate forcers implies uncertainty and inventory data availability issues.

466
Reaching consensus on cross-cutting issues
F. Verones, NTNU / Department of Energy and Process Engineering
Consistency across impact categories is important, in order to facilitate and enable comparisons across impact pathways. There are multiple issues that need to be dealt with in a cross-cutting manner and not all of them can be resolved in a simple manner. The focus of last year's work of the cross-cutting issues task force has focused on spatial aspects, normalization, uncertainty, reference states consensus for endpoint units and metrics for human health, ecosystem quality and resources, as well as a glance towards how current life cycle assessment (LCA) can be related to socioeconomic indicators. There is an unanimous consensus to keep DALY (Disability Adjusted Life Years) as endpoint indicator. We acknowledge that this does already contain a weighting, which is however internationally well-accepted. Endpoint indicators for ecosystem quality need to reflect species disappearance at a global level. There are different approaches how this can be reached and consensus is required. It is especially important that method developers provide the means to convert different units, such as PDF and PAF (Potentially disappeared/affected fraction of species). This will ensure full consistency between different impact categories. A preliminary consensus was reached that the vulnerability of different species or ecosystem types needs to be included. Models for doing so within LCA are being developed, but will need further investigation for consensus-finding. Especially important for ecosystem quality is also the discussion of reference states. It is difficult to find one common reference state across all areas of protection or all impact categories within one area of protection. We therefore propose to group impact categories in a meaningful way (e.g. based on ecosystem type affected), in order to share one common reference state. Other sub-tasks, like finding consensus on an optimal

spatial level, approaches for normalization and weighting, as well as the metric for resources are at the time of writing in discussion, without having reached a final recommendation yet. We would also like to stress that most recommendations are aimed for an immediate use. We acknowledge that LCA is a very dynamic field with many ongoing developments in terms of operational methodologies and refinements and we encourage further development and investigation that in future could lead to adapted recommendations.

467
Mainstreaming life cycle thinking through a consistent approach to footprints
b. ridoutt, CSIRO
Over recent years, footprints have emerged as an important means of reporting environmental performance. Some individual footprints have become quite sophisticated in their calculation procedures. However, as an overall class of environmental metrics they have been poorly defined, having a variety of conceptual foundations and an unclear relationship to LCA. The variety and sometimes contradictory approaches to quantification have also led to confusing and contradictory messages in the marketplace which have undermined their acceptance by industry and governments. In response, a task force operating under the auspices of the UNEP/SETAC Life Cycle Initiative project on environmental Life Cycle Impact Assessment has been working to develop generic guidance for developers of footprint metrics. The initial work involved forming a consensual position on the difference between footprints and existing LCA impact category indicators. In short, footprints are deemed to have a primary orientation toward society and nontechnical stakeholders and report only on selected topics of concern. On the other hand, LCA impact category indicators have a primary orientation toward technical stakeholders and report in relation to a larger framework designed for comprehensive evaluation of environmental performance and trade-offs. The task force has also developed a universal footprint definition, as an essential prerequisite for the development of more detailed guidance. In parallel to Area of Protection, we introduce Area of Concern. In the same way that LCA uses impact category indicators to assess impacts that follow a common cause-effect pathway toward Areas of Protection, footprint metrics address Areas of Concern. The critical difference is that Areas of Concern are defined by the interests of stakeholders in society rather than the LCA community. In addition, Areas of Concern are stand-alone and not part of a framework intended for comprehensive environmental performance assessment. The Area of Concern paradigm is needed to support the development of footprints in a way that fulfils their distinctly different purpose. Accordingly, footprints are universally defined as metrics used to report life cycle assessment results addressing an Area of Concern. The task group is now actively working on detailed guidance. One priority topic is the acceptable use of aggregation and weighting where the Area of Concern requires the use of multiple impact assessment models.

468
Product environmental footprint (PEF): improving life cycle impact assessment
M. Galatola, European Commission / DG Environment
Regarding the European policy context, the presentation will continue by presenting the consensus process initiated by the European Commission, aiming at covering land use related impact at midpoint, water related impact, respiratory inorganics and resource depletion to be used in the context of the Product Environmental Footprint (PEF) studies. Progress on this impact assessment harmonization process will also be presented in this session.

469
Life cycle impact assessment models for PEF: assessment of models and applicability challenges
S. Sala, European Commission - Joint Research Centre / Sustainability Assessment unit; R. Pant, European Commission / Institute for Environment and Sustainability
Regarding the European policy context, the presentation will continue by presenting the consensus process initiated by the European Commission, aiming at covering land use related impact at midpoint, water related impact, respiratory inorganics and resource depletion to be used in the context of the Product Environmental Footprint (PEF) studies. Progress on this impact assessment harmonization process will also be presented in this session. The session will end by a stakeholder presentation from industry and government workshop representatives and general feedback from session participants.

The sustainability of wine production in Europe

470
Ecosystem services and soil biodiversity in French vineyards
A. Nicolai, M. Guérnion, D. Cluzeau, University of Rennes; J. Gómez, G. Guzmán, University of Córdoba; P. Strauss, Austrian Federal Agency for Water Management; D. Popescu, A. Hoble, C. Bunea, Research Station for Viticulture and Enology Blaj; M. Potthoff, H. Bergman, University of Göttingen; S. Winter, J. Zaller, University of Natural Resources and Life Sciences Vienna
Essential ecosystem services provided by viticultural landscapes result from diverse communities of above- and belowground organisms and their interactions. As a result of management intensification in the last century several ecosystem services were affected leading to high rates of soil erosion, degradation of soil structure, soil fertility, contamination of groundwater and decrease of longevity of vines etc. Here we report how management intensity affects biodiversity of aboveground and belowground biota as well as their impact on ecosystem services in terms of regulating services in the agro-ecosystem, provisioning services and cultural services. Some alternative techniques and conservation measures that have the potential to mitigate the negative effect on biodiversity were introduced in some wine regions, thereby restoring ecosystem services. Furthermore, the impact of landscape structure on biodiversity and ecosystem services in vineyards is currently investigated in the Biodiversa project “VineDivers”.

Study of the variability of a vineyard sensitivity to fungus diseases in order to adapt chemical input: a priori zoning of Physiological Behavior Units (PBU) using precision viticulture techniques
m. raynal, B. DELFOUR, C. DEBORD, M. VERGNES, A. BENNABI, Institut Français de la Vigne et du Vin; M. GEORGES, R. FULCHIC, J. SERVANT, Château Léoville Las Cases
The systemic analysis of the performance of a vineyard at the scale of a wine-making exploitation is made possible by the use of sensors stemming from so called precision techniques, which allow precise and exhaustive geo-located measures. The aim of our study is to exploit this kind of data and evaluate their information using geographical information systems (GIS) and crossing different layers representing characteristic and independent variables of the production system. The goal is then to elaborate an à priori zoning, likely to explain variations of the physiological development of vines and possible differences of the plants susceptibility to fungus diseases. The study is based on the combination of two maps established on the property of Chateau Léoville Las Cases in the Medoc area of the Bordeaux vineyard (France). These maps represent the behaviour of the two compartments, soil and plant, respectively determined by means of electric resistivity (R) and biomass index (B) measures. Three levels - low, medium, high- are defined for each type of data. The combination of these indicators allows the elaboration of 9 classes of islets, named Physiological Behaviour Units (PBU), whose distribution is bounded by the GIS on the whole vineyard. Six of these nine PBU were selected by exclusion of the medium class of the biomass index. Each PBU is replicated twice, thus establishing an observation device of 12 PBU likely to identify differences in terms of physiological development and disease susceptibility. For this purpose, treated and non-treated zones were delimited for each PBU, and a weekly monitoring of these areas has been performed during the 2014 and 2015 crop years. The first years' results of the study show that the PBU concept proposed seem to correlate with some of the significant variations observed for physiological and sanitary criterions.

Biodegradability assessments of organic substances and polymers

475
Chemical analysis and measurement of biomass to enhance interpretation of hydrocarbon solvent biodegradability tests
C. Hughes, Shell International Limited / Shell Health; D. Brown, Shell Global Solutions International B.V.; G. Whale, Shell Health / Shell Health
Biodegradability is a key parameter for environmental hazard and risk assessment of chemicals. This is typically assessed experimentally following the OECD 301 A-F series of ready biodegradability tests in the first instance. These tests measure the biodegradation of a chemical under stringent conditions, and as such are considered a screening test for readily biodegradable substances. The results of these tests are used extensively both within a regulatory context and to support marketing claims on product biodegradability. However, these methods do have

their limitations, particularly when they are used to assess the biodegradation of complex, volatile and/or poorly water soluble substances. Recent investigations with GTL products have highlighted these issues. In particular, the inclusion of specific chemical analysis in biodegradation studies (not always a guideline requirement) has shown that disappearance of test substances from biodegradation systems is often far greater than is suggested by respirometric measures alone. This is indicative that either the material has been lost from the test system through abiotic processes (e.g. volatilisation), or that it has not been completely mineralised (e.g. it has been used as a carbon source to increase microbial biomass). The OECD 301F test was found to be more suitable for testing such substances than 301B, because it utilises a sealed system and therefore limits losses due to volatility. In this study a number of hydrocarbon solvents have been tested using OxiTop®-C test systems, following the OECD 301F test method. In addition to measuring biodegradation by biological oxygen demand (BOD), additional techniques have been incorporated to enhance the interpretation of results. Analysis by GC-FID and by TIC/TOC has been conducted to assess the presence of residual test substance and other metabolites, and the increases in microbial biomass have been measured to give an indication of the amount of carbon used by the inoculum to increase its biomass, rather being completely mineralised. In addition, abiotic controls have been run to assess removal from processes other than microbial degradation. Using this combination of additional measures and analyses, it is possible to account for a greater percentage of the total material tested, and therefore to improve the interpretation of these tests.

476
Approaching chemicals' persistence through a new strategy of use of RBT tests
F. Brillet, University of Nantes / Microbiology; A. Maul, Univeristy of Lorraine / Applied Statistics; M. Durand, University of Nantes / UMR CNRS GEPEA CEBAC Laboratory; T. Gerald, University of Nantes / Microbiology
Approaching chemicals' persistence through a new strategy of use of RBT tests Brillet François[1], Maul Armand[2], Durand Marie-José[1] and Thouand Gérald[1] [1]Université de Nantes, UMR CNRS 6144 GEPEA, IUT Génie Biologique, La Roche sur Yon, France. [2]Université de Lorraine, LIEC-UMR CNRS 7360, Metz, France gerald.thouand@univ-nantes.com With millions of organic chemicals released every day into our environment, Europe and other continents are confronted with increased health and environmental problems. Even if strict regulations are imposed upon industry to ensure that they prove the harmlessness of their substances during marketing authorization, not all testing procedures are designed to cope with the complexity of the environment. This is especially true for the evaluation of persistence through biodegradability assessment guidelines. Our new approach has been to adapt *in vitro* biodegradability assessment to the environmental conditions and model the probability for a biodegradation test to be positive in the form of a logistic function of both the temperature and the cell density. Here, a proof of this new concept is proposed with the establishment of 3D biodegradability profiles of 6 chemicals (including the controversial glyphosate) between 4 to 30 °C and 10^4 to 10^8 cells ml^{-1} as can be environmental compartments in time and space. The results show a significant increase of the predictive power of existing lab scale tests and the creation of new indicators to quantify environmental persistence. Key words: Biodegradability Assessment, Environmental Persistence

477
Screening for Persistence: Tools to Determine Mineralization and Estimate Kinetics in Water, Water-Sediment and Soil
T. Junker, ECT Oekotoxikologie GmbH; A. Coors, ECT Oekotoxicologie GmbH; G. Schüürmann, Helmholtz centre for environmental research - UFZ / Department of Ecological Chemistry
Standardized biodegradation tests provide data that are required for persistence assessment (e.g. under REACH). In a first step, clearly non-persistent substances are identified within a persistence screening based on results from water-only ready biodegradability tests (RBTs) and QSAR models. However, RBTs providing quantitative biodegradation data for sediment and soil are still lacking. Hence, predictions of degradation rates and half-lives of organic compounds by QSAR models are mainly based on qualitative experimental biodegradation data related to water-only test systems. Moreover, half-lives related to water are extrapolated to soil and sediment by multiplication with default factors. Within this study, the existing experimental screening test method to determine biodegradation in water according to OECD 301C (MITI, Ministry of International Trade and Industry, Japan) was modified to develop new test systems on the screening test level for water-sediment (WSST, Water-Sediment Screening Tool) and soil (SST, Soil Screening Tool). The test systems were applied to determine mineralization rates and kinetics of 15 organic compounds in water, water-sediment and soil (45 tests in total). Resulting degradation curves were fitted by different non-linear regression models and kinetic parameters were derived using the regression model with the best fit. The experimental results were verified based on (i) validity criteria according to OECD 301, (ii) reproducibility of results, and (iii) comparability with biodegradation data from well-established test methods. In addition, options how the determined mineralization rates and kinetics could be applied within a persistence screening are presented. The new screening-test systems WSST and SST proved to be suitable tools to determine reproducible and sound quantitative biodegradation data including biodegradation kinetics for water-sediment and soil, respectively, that could be applied in the regulatory context (e.g. within a persistence screening). The observed substance-specific variation of biodegradability in different environmental compartments provides strong evidence that extrapolation of half-lives from water to sediment and soil by use of default factors should be avoided. Beyond that, the test systems can be used for building up a database of screening-level biodegradation information across major compound classes, which can serve as reference set for subsequent research into respective in silico models.

478
Identifying limitations of the OECD water-sediment test (OECD 308) and developing suitable alternatives to assess persistence
K. Fenner, ETH Zürich/Eawag; M. Honti, MTA-BME Water Research Group, Hungarian Academy of Sciences; T. Junker, ECT Oekotoxikologie GmbH; P. Shrestha, Fraunhofer IME - Institute for Molecular Biology and Applied Ecology; S. Hahn, Fraunhofer ITEM / Chemical Risk Assessment; M. Matthies, University of Osnabruck; D. Hennecke, Fraunhofer IME - Institute for Molecular Biology and Applied Ecology / Ecological chemistry
The OECD guideline 308 describes a laboratory test method to assess aerobic and anaerobic transformation of organic chemicals in aquatic sediment systems and is an integral part of tiered testing strategies in different legislative frameworks for the environmental risk assessment of chemicals. Over the years, several shortcomings of the OECD guideline 308 have been identified and its usefulness for persistence and exposure assessment has been questioned. On October 6, 2015, a final stakeholder workshop of the Cefic-funded project “LRI ECO18 – Improved strategy to assess chemical persistence at the water-sediment interface” was held. The goal of this workshop was to summarize stakeholder perspectives on the status quo of both OECD guidelines 308 and 309, and to complement this with a dissemination of the findings of the project LRI ECO18. In this presentation, the main outcomes of the workshop will be presented, i.e., (i) sharing of industry and regulatory experience with OECD 308 and 309 in different regulatory contexts, (ii) identification of major issues and knowledge gaps with respect to OECD 308 and 309, and (iii) presentation of main outcomes and recommendations from LRI ECO18 project [1-3]. Biodegradation of squalane by a Pseudomonas aeruginosa strain and bioavailability considerations
S. Solanki, D. Dasgupta, IIT Bombay / Centre for Environmental Science and Engineering; S. Mukherji, Indian Institute of Technology / CESE
Very few studies have reported bacterial degradation of the long chain length, acyclic isoprenoid, squalane (2,6,10,15,19,23-hexamethyltetracosane) although there are several reports on biodegradation of smaller chain length isoprenoids, such as pristane and phytane. The low aqueous solubility and structural complexity limits the bioavailability of branched alkanes to most strains. This study reports squalane biodegradation by a *Pseudomonas aeruginosa* strain RS1 isolated from refinery sludge that could utilize it as sole source of carbon and energy after a long acclimatization period was provided. It exhibited specific growth rate in the range 0.19-0.22 h^{-1} over the squalane concentration range of 250 - 750 mg/L in Bushnell-Haas mineral media. The maximum extent of degradation (67%) was achieved after 96 h for squalane concentration 250 mg/L where abiotic loss was less than 20%. Negligible extracellular release of biosurfactants was observed. Contact angle measurements revealed that the cell surfaces of squalane grown cells were moderately hydrophobic, thus, indicating direct interfacial uptake of squalane. However, the adherence to n-hexadecane and squalane in the bacterial adhesion to hydrocarbon (BATH) assay was unexpectedly low (less than 30%). This apparent anomaly may be explained by the fact that BATH assay is not a true measure of hydrophobicity since it is likely to be affected by solution phase interactions, such as, electrostatic interactions. A similar mechanism was employed by this strain for degrading the aromatic hydrocarbon, pyrene, at relatively high rate compared to other pyrene degraders This is the first study reporting degradation kinetics and bioavailability considerations for squalane uptake and thus provides insight on degradation of branched alkanes in petroleum.

Mercury Biogeochemistry and Policy

480
Mercury concentrations in suspended particulate matter, water and mud-sediment up and downstream from old and recent gold mining sites in French Guiana

J. Hellal, BRGM; M. Moisan, Bureau de recherches géologiques et minières BRGM; l. lanceleur, IPREM CNRS UPPA / IPREM UMR CNRS; R. Vigouroux, Hydreco; J. Schäfer, Université de Bordeaux; V. Laperche, Bureau de recherches géologiques et minières BRGM

Although the use of mercury (Hg) for gold mining has been officially banned in French Guiana since 2006, there are still reasons to be wary of its occurrence in river water and its impact on local populations. In fact, gold-mining generates intense soil erosion and high turbidity in the rivers downstream from mining sites. This contributes to Hg pollution and dissemination both via the remobilization of Hg naturally present in the soils and the release of metallic Hg from the gold recovery process. In the affected rivers, Hg transport and speciation is mainly controlled by the suspended particulate matter (SPM) rather than remaining dissolved. The aim of this study is to understand and quantify the fate of this SPM-associated Hg along the Boulanger River affected by old and new gold mining activities. Furthermore we provide recent data (2012) essential to evaluate the efficiency of legal gold mining companies in restoring and re-planting exploited zones to control erosion, river turbidity and SPM transport. Inorganic Hg(II), monomethylmercury (MMHg) and turbidity measurements were measured in water, SPM and mud-sediment collected along the Boulanger River, from the spring down to its confluence with the Orapu River. The intensity of gold-mining in this area has been up and down through the last century and presents contrasting conditions with old and recently exploited areas. Dissolved Hg (HgD) levels were low (1-2 ng.L^{-1}) and consistent with previous data known for the Amazonian area. Dissolved MMHg concentrations represented up to 8% of HgD which is higher than previous results (around 2%). Some relationships occurred between Hg concentrations in mud-sediment and turbidity values which both decreased downstream from the mining sites, then stabilized at 4-5 km further down. Hg contents in the mud-sediment show the impact of old and new gold mining practices. These results show that even though Hg use was banned from French Guiana 6 years ago, present gold mining practices still release significant amounts of Hg into the rivers. Survey intensification in French Guiana river systems should provide a more complete data set, essential to change gold mining practices and to reduce SPM and Hg contamination of the aquatic environment.

481

In situ biomonitoring of mercury bioavailability and transfer in a former gold mining area (French Guiana).

F. Gimbert, University of Franche-Comte / UMR ChronoEnvironnement; B. Smith, University of Bourgogne Franche-Comté, UMR UFC/CNRS 6249 / UMR ChronoEnvironnement; E. Tessier, LCABIE-IPREM UMR 5254 CNRS-UPPA; D. Amouroux, Laboratoire de Chimie Analytique Bio Inorganique et Environnement, UMR CNRS IPREM5254, University Pau.; N. Bousserrhine, Université Paris-Est Créteil / Bioemco; B. Ferrari, Ecotox Centre CH

Gold mining activities have a considerable impact on the entire ecosystem, including terrestrial and aquatic compartments. Beside the physical degradation of soils and river network, artisanal small-scale gold mining also leads to the release of mercury (Hg) in the environnement. The sources of Hg are both anthropogenic (from fine gold particles amalgamation) and geogenic (from weathering of parent rocks and long-term atmospheric deposition). Mercury contamination of the aquatic food web constitutes both an environmental and sanitary risk since local populations largely feed on topchain predator fishes which exhibit high Hg concentration. Among Hg species, monomethyl-Hg (MMHg) represents the most bioaccumulative and toxic form. The objective of the present study was to investigate the bioavailability and the transfert potential of Hg in a former gold mining area in French Guiana using chironomid larvae, key organisms of the aquatic ecosystem functionning and food chains. Hence, in an active biomonitoring campaign, we investigated (i) inorganic-Hg (IHg) and MMHg toxicokinetics in larvae encaged in the field and (ii), by mean of designed exposure devices, the contributions of water and sediments to both IHg and MMHg uptake. The study site was a former goldmine flat of the Combat Creek catchment (French Guiana) exploited until 2010. We used calibrated fourth instar larvae of *Chironomus riparius* bred in the laboratory (IRD Cayenne) under controlled conditions. Larvae were exposed in two different types of cages allowing the contribution of water and sediments in IHg and MMHg bioaccumulation to be estimated. Mercury speciation was conducted (GC-ICP-MS) both in unsoluble (exoskeleton, gut content and granules) and soluble (cytosol) fractions. Although IHg did not accumulate, MMHg was bioavailable to chiromid larvae and mainly accumulated in the cytosolic compartment. Moreover, sediments appeared as an important source of MMHg as testified by the higher uptake rate modelled in larvae exposed to both water and sediments compared to water exposure only (0.57 and 0.18 ng.g^{-1}.d^{-1}, respectively). Hence, the active biomonitoring using *C. riparius* larvae allowed to efficiently estimate MMHg bioavailability and its potential of transfer in the trophic web since the fraction stored in the cytosolic compartment can be considered as trophically available to most, if not all, predators.

Linking variation in natural solar radiation with seasonal methylmercury dynamics in freshwater lake systems

S. Klapstein, Acadia University / Earth Environmental Science; S. Ziegler, Memorial University of Newfoundland / Earth Science; D. Fischer, Bayer CropScience LP / RD Environmental Safety; N.J. O\'Driscoll, Acadia University / Department of Earth and Enviromental Science

Methylmercury bioaccumulation in biota is a serious concern for mercury sensitive ecosystems far from direct point sources of pollution. Low buffering capacity in soils and high atmospheric deposition of mercury and acid rain from anthropogenic sources can enhance the solubility and transport of metals into waterways. Plentiful wetland environments and well-mixed lakes make studying the processing controlling methylmercury concentrations in water dynamic and complex. While much is know about mercury methylation in freshwater, much less is known about demethylation. The loss of methylmercury from the water column of lakes is dependent on several processes including adsorption, deposition to sediments, and demethylation. Microbial demethylation in water columns is very slow, therefore a daytime photodemethylation facilitated by solar radiation can dominate methylmercury removal from the water column. To better quantify the photodemethylation potential within lakes we must determine a) the variation in photoreactive compounds such as dissolved organic matter (DOM) and iron (Fe) and b) the availability of solar radiation with depth in water columns. Freshwater lakes were chosen in Kejimkujik National Park (44.23°N, 64.13°W) to include a wide range in dissolved organic carbon (DOC) and Fe concentrations. Water samples were collected over 3 years and analyzed for ultraviolet (UV)-visible absorbance, DOC, dissolved ions, total mercury, and methylmercury concentrations. Floating sensors for UV, photosynthetically active radiation (PAR), and temperature were also installed in two lakes of contrasting DOC concentrations. The depth of 95% UV attenuation was 40-50 cm in the lower carbon lake compared to 10-20 cm in the higher carbon lake. The effect of rainfall on UV attenuation was also less in the lower carbon lake compared to the higher carbon lake, most likely due to a difference in catchment area. Seasonal alterations to the solar angle of incident radiation strongly controlled the amount of solar radiation entering lake water surfaces and therefore outlined a possible photoreactive season or period within each year. These observations suggest that photodemethylation of methylmercury in lake water columns may be limited to a short period of approximately 4 months a year at 44°N. Overall, these field observations provide fine resolution solar radiation data and excellent temporal resolution over 3 years for mercury and carbon cycling.

483

Dietary transfer of Hg from Elodea nuttallii to Gammarus fossarum

R. Beauvais-Flueck, Institute Forel Earth and Environmental Sciences; a. chaumot, Irstea / UR MALY Laboratoire Ecotoxicologie; F. Gimbert, University of Franche-Comte / UMR ChronoEnvironnement; O. Geffard, Irstea / UR MALY Laboratoire Ecotoxicologie; C. Cosio, Geneva University / Institute Forel Earth and Environmental Sciences

In the aquatic environment, the organic form of Hg, methyl-Hg (MMHg) and inorganic Hg (IHg) are both toxic, but MMHg has been shown to biomagnify through food chain while IHg does not. Nonetheless, the precise factors controlling the transfer of Hg from primary producers to heterotroph consumers remains poorly understood. Macrophytes are key organism of shallow aquatic environment in which MMHg is produced, and have been identified as having a role in Hg transfer to food webs. The objective of this study was therefore to assess how the compartmentation of IHg and MMHg in a representative macrophyte, *Elodea nuttallii*, affects their bioaccumulation through dietary transfer in *Gammarus fossarum* chosen as surrogate species for aquatic herbivores and decomposers. Bioaccumulation of Hg in *E. nuttallii* was higher for cell wall than intracellular in line with previous studies showing an important role of binding of Hg in cell wall in *E. nuttallii*. Our data suggest no substantial demethylation or methylation during bioaccumulation in *E. nuttallii in planta* or in water. THg and MMHg concentrations increased in Gammarids in correlation with concentration found in *E. nuttallii*. MMHg was more transferable than IHg, based on THg, but a significant part was demethylated during the feeding, while no methylation was observed in the IHg exposure. Cell wall results in higher concentrations than intracellular, suggesting that Hg in cell wall in form of MMHg and IHg was significantly assimilated by Gammarids. Significant uptake fluxes were estimated by the first-order model: uptake fluxes in Gammarids were higher for cell wall than intracellular, while similar uptake rates were observed for IHg and MMHg. In conclusion, *G. fossarum* is able to feed on *E. nuttallii* and accumulates Hg from **intracellular** and cell wall **compartments**. In line with literature, when looking at THg, consumption of MMHg-exposed plants leads to slightly higher accumulation of Hg than IHg-exposed plants, but we observed a significant demethylation of MMHg in Gammarids *vs* plants. Opposite to literature, we did not observed a significant biomagnification of MMHg. In sum, although the subcellular metal distribution is determinant for many consumers that are unable to assimilate the insoluble fraction of cell **walls**, the digestive strategies to handle food of the consumer is also important. Differences in primary producers and consumers species composition may significantly influence the fate of Hg in food webs.

Concentrations of mercury in porbeagle shark Lamna nasus

E.E. Nicolaus, Cefas Lowestoft Laboratory / Environment and Ecosystems; V.

Bendall, T. Bolam, Cefas Lowestoft Laboratory; T. Maes, Cefas / EQT; J. Ellis, Cefas Lowestoft Laboratory
Concentrations of mercury in three tissues of porbeagle shark *Lamna nasus* (n = 33) were determined. While all specimens exceeded OSPAR's Background Assessment Concentrations of 0.035 mg kg^{-1}, Hg concentrations in either the red or white muscle that exceeded European regulations for seafood were observed in one-third of specimens. Hg concentration, however, increased with length, and all fish >195 cm had concentrations >1.0 mg kg^{-1}, with a maximum observed value of 2.0 mg kg^{-1}.

485
Spatial and temporal monitoring of total mercury and monomethylmercury in fish from European freshwaters
B. Knopf, R. Nguetseng, Fraunhofer IME   Institute for Molecular Biology and Applied Ecology / Environmental Specimen Bank and Elemental Analysis; R. Klein, Trier University; J. Koschorreck, Umweltbundesamt; H. Ruedel, Fraunhofer IME - Institute for Molecular Biology and Applied Ecology / Environmental Monitoring
For the implementation of the European Water Framework Directive (2000/60/EC) an environmental quality standard (EQS) of 20 µg/kg mercury (Hg) in fresh weight of aquatic organisms was derived (EU Directives 2008/105/EC, 2013/39/EC). Because of their differing chemical behavior and ecotoxicity (e.g., secondary poisoning of predators by MeHg) inorganic Hg and organic Hg (mainly monomethylmercury, MeHg) should be evaluated differently. However, in aquatic organisms only determination of total mercury concentrations is required for the WFD compliance monitoring. Here we quantified also the MeHg levels in the fish samples to allow a better risk assessment of the Hg residues. From a previous monitoring program bream (*Abramis brama*) collected from different European freshwaters were available. In the period 2007-2013 the rivers Tees/UK, Mersey/UK (no sampling 2009-2011), Götaälv/SE (no sampling 2009-2011), Western Scheldt/NL, and Rhône/FR as well as a lake (Belau/DE) were covered. Pooled muscle tissue samples of 15 fish per site were homogenized and analyzed for total Hg with a Direct Mercury Analyzer as well as for MeHg by SID-GC/ICP-MS (species isotope dilution-gas chromatography - inductively coupled plasma-mass spectrometry). The results of the total Hg analyses of the fish samples from European freshwaters were then compared to the long-term freshwater fish monitoring data of the Environmental Specimen Bank operated by the GermanFederal Environment Agency. Data reveal that both for the fish from the European as well as from the German river sites EQS were clearly exceeded. Only data for the one German lake site investigated revealed total Hg levels in the range of the EQS in recent years. Regarding the MeHg fraction of the total Hg literature data could be confirmed which report high MeHg fractions in the range of 70-100 %.

Mechanistic toxicology of engineered nanomaterials: state of the art and future perspectives (I)

Oxidative stress response of the aquatic macrophyte Hydrilla verticillata exposed to nanoparticulate and bulk TiO2
A. Okupnik, Technische Universität Berlin; S. Pflugmacher, Technische Universität Berlin / Department of Ecological Impact Research and Ecotoxicology
Nanotechnology is a rapidly growing industry with manufactured titanium dioxide nanoparticles (TiO_2-NPs) being one of the most commonly employed metal oxide NPs. Due to increasing production volumes concerns about the fate and behaviour of nano-TiO_2 in the aquatic environment have arisen, as water reservoirs will be the final destination of TiO_2-NPs. Currently, there is emerging research activity concerning the ecotoxicology of TiO_2-NPs in aquatic ecosystems. However, biochemical studies investigating the effect of TiO_2-NPs on oxidative stress related parameters in aquatic macrophytes are scarce, despite their important role in aquatic habitats. In the present study, oxidative stress effects in *Hydrilla verticillata* caused by TiO_2-NPs of different cristallinity status were investigated and compared to a bulk sized counterpart. Macrophytes were exposed to different concentrations of TiO_2-NPs (0, 0.01, 0.1, 1, 10 mg/L) for 24 h, and thus experimental setup included currently predicted levels of nano-TiO_2 in surface waters. Additionally, the investigated TiO_2-NPs contributed varying crystalline status (anatase, rutile, P25-mixed phase) to assess a potential influence of crystalline phases on oxidative stress responses. As oxidative stress related parameters the level of hydrogen peroxide (H_2O_2), reduced and oxidized glutathione (GSH and GSSG) and activities of the antioxidative enzymes peroxidase (POD), catalase (CAT) and glutathione reductase (GR) were measured. Whereas POD was not considerable activated in this study, results imply an activation of the enzymatic defense system, as increased CAT and GR activities were observed. No significant changes in enzyme activities were assessed for the treatments with bulk TiO_2 and moreover, such exposed plants exhibited lower enzyme activities at all concentration steps, suggesting a nano-specific influence on antioxidative defense mechanisms in *H. verticillata*. All TiO_2-NP concentrations dropped the GSH/GSSG ratio, indicating a high GSH-dependent metabolic activity to protect against the destructive effects of reactive oxygen species (ROS) generated during nano-TiO_2 exposure. Furthermore, the glutathione status seems to be a sensitive marker for changes in the cellular redox state of macrophytes. As the level of H_2O_2 was solely elevated after exposure to 10 mg/L of P25, adaptive metabolic mechanisms of *H. verticillata* are probably able to cope with environmentally relevant concentrations of TiO_2-NPs.

487
Does a coating matter? Antioxidant enzymes activities in the water flea Daphnia magna exposed to modified copper oxide engineered nanomaterials.
Z. Gajda-Meissner, Heriot-Watt University / School of Life Sciences; M. Hartl, Heriot-Watt University / Centre for Marine Biodiversity and Biotechnology School of Life Sciences; T.F. Fernandes, Heriot-Watt University / School of Life Sciences
Production of reactive oxygen species (ROS) has been described as a general pathway of toxicity induced by various metal based engineered nanomaterials (ENMs) and other chemicals leading to oxidative stress Coating-related changes in three antioxidant enzymes' activities in the freshwater flea *Daphnia magna* were assessed, based on information obtained in acute and chronic toxicity tests. Experiments on biochemical responses following exposures to different CuO ENMs were focused on the activities of catalase (CAT), superoxide dismutase (SOD) and glutathione-S-Transferase (GST) after 2, 6 and 24 hours of exposure. To minimise variability in the response to the analysed CuO ENMs, a single laboratory clone of *D. magna* (clone GG4) cultured at Heriot-Watt University, was selected for this study. Cultured juveniles aged 5-8 days were used for biochemical analysis: 450 for CAT, 450 for SOD, 450 for GST and protein analyses, with three replicates per treatment. The animals were exposed to sublethal CuO ENM concentrations, corresponding to EC50 values obtained after 48 hours of exposure. Enzyme activity responses varied across the ENM panel. SOD, CAT and GST, which are considered the most important antioxidant enzyme systems in invertebrate species, showed different responses across the different surface modifications and time of exposure. After two and six hours of exposure *Daphnia* juveniles exposed across the ENM panel did not show significant increase in SOD activity. After 24 hours of exposure, SOD activity significantly increased for animals exposed to CuO, CuO-COOH and CuO-NH_3 ENMs. After 2 hours no significant differences between treatments were observed for the GST activity across all tested chemicals. The GST activity significantly increased after exposure to CuO-COOH and CuO-NH_3 ENMs for 6 hours, and for CuO-PEG after 24 hours exposure. No significant effects on CAT were observed after 2 and 24 hours of exposure; only CuO-PEG ENM showed marginal but not significant increase in CAT activity after 24 hours. Significantly increased CAT activity was observed following exposure to unmodified copper oxide and CuO-NH_3 ENMs after 6 hours. The most sensitive endpoints after 6 hours were CAT and GST assessments and SOD, after 24 hours exposure. Based on the above results it is apparent that ROS play an important role in the toxicity pathway observed, and the pattern observed depends on the CuO ENMs surface modification and time of exposure.

Secreted protein eco-corona mediates uptake and impact of 'next-generation nanoparticles' on Daphnia magna
F. Nasser, University of Birmingham / Geography Earth and Environmental Science; I. Lynch, Univeristy of Birmingham / Geography Earth   Environmental Science
Nanoparticles (NPs) have at least one external dimension between 1-100nm. The small size of NPs gives them a large surface area to volume ratio providing them with exclusive properties that differ from bulk material of the same chemical composition. As a result, these unique materials have found numerous applications in industrial fields leading to their inevitable release into the environment during use or at the end of their life cycle. NPs are known to adsorb molecules such as proteins from their environment, to form an eco-corona, which ultimately changes the NP identity and how it interacts with organisms. Secretion of biomolecules is a well-established component of both intra-species communication and predator-prey response in aquatic food-chains and therefore the impact of such secretions on NP uptake and ecotoxicity must be investigated. Here we report some initial studies, using model spherical polystyrene NPs which mimic plastics that degrade slowly in the environment, resulting in build-up of nano-plastic in fresh water systems. We also look at various shaped and charged 'next-generation NPs' including gold NPs with different morphologies whose release into the environment is increasingly likely due to the heightened use of these NPs in medical systems. Finally, we look at several novel perovskite NPs, which are increasingly used in solar cells. For all NPs, the impact of the secretion of biomolecules by *Daphnia magna* on the NP uptake, retention and toxicity was assessed. Interestingly, in all cases studied to date, a pre-formed eco-corona from *D. magna* secreted biomolecules resulted in enhanced NP toxicity, related to enhanced uptake and retention of the particles, and in some cases to enhanced oxidative stress.

Comparative evaluation of acute and chronic ecotoxicity of Copper Oxide nanoparticles on the pond snail Lymnaea stagnalis

V. Ricottone, Heriot-Watt University / School of Life Science; T. Henry, Heriot-Watt University / School of Life Sciences; V. Stone, Heriot-Watt University / School of Life Science; T.F. Fernandes, Heriot-Watt University / School of Life Sciences
Nanotechnology is a rapidly developing field in the 21st century, and commercial use of nanomaterials for novel applications is increasing exponentially. Copper oxide nanoparticles (CuO NPs) are frequently employed for their antimicrobial properties in antifouling paints. Their extensive use can contaminate aquatic ecosystems. The objective of this study was to evaluate and compare the aquatic toxicity of CuO NPs through acute and chronic toxicity tests with different life stages of the snail *Lymnaea stagnalis*, a representative organism of the benthic ecosystem. Acute waterborne exposure was focused on the evaluation of the acute lethal toxicity of CuO NPs to juveniles (7-9 day old) of the snail *L. stagnalis* exposed for 96h at 20°C in a static experiment, either in the nano form of CuO NPs or ionic form, as $CuSO_4*5H_2O$. The LC50 value estimated in tests with $CuSO_4$ ($LC50_{96h}$ = 5.7 µg L^{-1} Cu) was 400 fold lower than that obtained for the tests with CuO NPs ($LC50_{96h}$ = 2500 µg L^{-1} Cu). Chronic toxicity tests aimed to investigate the effects of exposure CuO NPs on the reproduction to *L. stagnalis*. Young adult snails(22±2mm) were exposed to Cu as CuO NPs at 20°C for 30 days in a semi-static experiment. Endpoints such as: mortality, growth and behaviour alteration were also evaluated along with the reproduction parameters. $LC10_{30d}$ and $LC50_{30d}$ values estimated were respectively, 230 µg L^{-1} Cu and 480 µg L^{-1} Cu, indicating a 5 fold higher toxicity than the acute test. Additionally, exposure to CuO NPs showed significant effects ($p< 0.001$) on the growth and reproduction parameters relative to the control. Behavioural changes, such as respiration behaviour, were also observed in the Cu treatments. The experiments' results demonstrate a time-related increasing toxicity of CuO NPs on *L. stagnalis*, emphasizing the need for more chronic study to accurately evaluate the impact of nanomaterials in the real environment. Furthermore, long-term experiments using juveniles *L. stagnalis* exposed to CuO NPs are ongoing, evaluating growth and time-related expression profiles of antioxidant enzymes and heat shock proteins response in snails to thermal shock. Acute and chronic tests assessing the toxicity of safe-by-design CuO NPs and their fragmented products (FP) on *L. stagnalis* will be performed, applying the same experimental design used for evaluate the toxicity of the pristine CuO NPs. This research project is funded by the European FP7 project SUN "Sustainable Nanotechnologies".

Bioavailability of metal nanoparticles in a sediment dwelling organism: a study of transdermal and oral routes of uptake
R. Cross, C. Tyler, Biosciences College of Life and Environmental Sciences; T.S. Galloway, University of Exeter / Biosciences Department
Metal engineered nanomaterials (ENMs) are an emerging pollutant considered to be of risk to aquatic environments due to their inherent reactivity and high global production volumes. The behaviour of metal ENMs in aquatic sediment systems is dominated by transformations including aggregation, complexation with organic matter and in some cases dissolution of metal ions. Investigating ENM behaviour in sediments requires novel combinations of separation and microscopy techniques. This will allow us to correctly interpret the results from studies into the bioaccumulation of ENMs in benthic species. Using a combination of centrifugal ultrafiltration and Asymmetric flow Field Flow Fractionation (AF4) the size distribution and dissolution of both ceria (CeO2NPs) and silver (AgNPs) nanoparticles was followed in a model sediment system over 6 days. The aim was to compare uptake through transdermal or oral routes. Two commercially relevant Ag NPs were chosen as test materials: one stabilised sterically with PEG (mono mPEG phosphonic acid ester), the other with an electrostatic stabiliser, citrate. The NPs had a primary particle size of 4-10 nm. A 5 day bioaccumulation exposure was conducted using the sediment dwelling oligochaete worm Lumbriculus variegatus. Organisms were either actively feeding (uptake through transdermal and oral ingestion) or non-feeding, achieved by utilising the species' natural mode of reproduction by clonal fragmentation, to yield non-feeding clones. Centrifugal ultrafiltration examined partitioning of CeO2 and AgNPs between the solid and liquid phases of the sediment and NP dissolution. AF4 was used to investigate the size distribution and preferential heteroaggregation between the CeO2 and AgNPs and other natural colloids present in the sediment pore waters. Results demonstrate that for CeO2 NPs, dissolution does not occur and there was no uptake of nanoparticles across transdermal pathways. Coating type (electrostatic or steric) also made no difference to bioavailability of these particles through ingestion. All three NP treatments were significantly more bioavailable than either the geogenic Ce present naturally in the sediments or micron sized CeO2. Results for Ag NPs are ongoing and will be reported in full during the presentation. Results will be discussed in the context of the transformations that the nanoparticles have undergone and their interactions with other natural colloidal materials in the sediments.

491
Effects of iron nanoparticles on primary cultures of human bronchial epithelial cells
L. Canivet, University of Lille 2; F. Denayer, Universite de Lille 2 Droit & Sante; P. Dubot, MCMC ICMPE UMR 7182; G. Garcon, J. Lo Guidice, University of Lille 2
Airways constitute the major route of exposure to atmospheric particulate pollutants. Furthermore, inhalation of fine and ultrafine particles contributes to their rapid transfer to the lung. Their size allows them to reach the deep lung, and the smallest of them can be transferred to the entire human body. Recent studies have demonstrated that exposure to atmospheric particulate was associated with an increased risk of morbidity and mortality related to respiratory and cardiovascular diseases. Indeed, with the complexity of the bronchial tree, inhaled ultrafine particles are in regular contact with lung epithelial cells and may favor the emergence of chronic inflammatory diseases (asthma, COPD, etc) With the emergence of nanotechnology and the increasing use of nanoparticles, a question emerges: "what are the effects of this nanoparticles on health?" The specific properties of nanoparticles such as their smaller size, larger surface area and higher reactivity are major points of concern. Consequently, an essential step in nanoparticle study is their physicochemical characterization in their pristine state, or suspended in an aqueous medium. In the present study, we aim to investigate the lung effects of iron-engineered nanoparticles (representative of industrial smoke emitted by metallurgical industries). After characterizing these particles at the physic-chemical level and verifying their capabilities to penetrate lung cells using transmission electron microscopy, we assessed their cytotoxicity on primary lung cells and their capacity to modulate gene expression and oxidative stress. After 6-h exposure of primary cells to low dose of iron-engineered nanoparticles, we highlighted expression modulations of genes involved in inflammation but we failed to detect a significant induction of oxidative stress.

Soil and water contaminants: evaluation, biomonitoring and bioindicators for effective management (I)

492
Which pollutant should we be measuring? - Broad spectrum screening provides multiple answers in a single run
L.P. Quinn, NMISA / Organic and BioAnalysis; R. Pieters, H. Bouwman, North-West University / Unit for Environmental Sciences and Management
There is still little information on which chemical pollutants are present in the South African environment. To prioritise economic investment in expensive analytical techniques, valuable information should first be gained from broad spectrum screening. A broad spectrum analytical screening technique was developed for the analysis of non-polar lipophilic compounds from abiotic and biotic matrices using comprehensive two- dimensional gas chromatography time of flight mass spectrometry (GC×GC-TOFMS). Once a specific compound class is identified, the method can then be used for quantification. This provides a powerful tool in optimising the amount of data that can be generated within a single analysis. A LECO Pegasus IV, comprehensive two-dimensional gas chromatography coupled to time of flight mass spectrometry (GC×GC-TOFMS) system was used with a non-polar Rxi®-5Sil MS primary column and a mid-polar Rxi®-17SilMS secondary column. The developed method was tested on sediment samples extracted using selective accelerated solvent extraction. Non-target compounds in complex samples can be provisionally identified due to the predictable compound grouping within the chromatogram (based on physiochemical properties) and full mass spectra collected. The analysed sediment samples from industrial areas indicated the presence of various PCBs, PAHs, PAH derivatives, as well as chlorinated PAHs, steranes , hopanes, and thiophenes associated with petrochemical contamination. In agricultural areas terpernoids, terphenyls and PAHs were prevalent with various pesticides. PAH, PCB and OCP concentrations were quantified successfully using the data collected in the same analytical run. This analytical technique allowed petrochemical contamination to be identified even though the initial focus of the study was PAHs, OCPs and PCBs. Petrochemical contaminants can be of concern to human and environmental health, especially PAHs and related compounds that are known human carcinogens. This data can then be used to justify a project focused on the presence of petrochemical contaminants in the South African environment.

493
Raman SERS monitoring of Acetylcholinesterase activity for the detection of pesticides
A. EL ALAMI, IMMM LE MANS; f. lagarde, Institute of molecules and materials of Le Mans / Institute of Materials and Molecules of Le Mans IMMM UMR CNRS; B. MIMOUNA, Faculté des Sciences Dhar Mehraz Fés / Laboratoire de Physique du Solide équipe polymères et nanomatériaux; P. Daniel, University of Le Mans / Institute of Materials and Molecules of Le Mans IMMM UMR CNRS
Pesticides are well-known chemical compounds highly toxic for health and environment with important economic consequences. Usually various methods are implemented to detect pesticides such as gas chromatography and high performance liquid chromatography, although these can't provide rapid, sensitive, simple and low-cost on-field detection. Over the last decade more sensitive and specific pesticides detection techniques have been explored, such as fluorescent and amperometric, even if they are not appropriate for routine application, they give a sum parameter of the presence of pesticides without any qualitative or

quantitative information on the individual analyte. In this work, we present a new Raman SERS biosensing system for the qualitative and quantitative detection of pesticides by measuring the Acetylcholinesterase (ACHE) activity. The Raman SERS is not only used for measuring the ACHE activity, but also the direct detection of pesticides individually. Gold nanoparticles (AuNPs) were used as dynamic surface-enhanced Raman spectroscopy (SERS) for sensitive monitoring of ACHE activity in the presence of very low levels of organophosphate and carbamate pesticide. The limit detection of paraoxon and carbaryl were determined at $4*10^{-14}$M and 1nM respectively. These results suggest that this biosensor could be used in the future for the non-selective detection of all ACHE inhibitors at low concentrations.

494
Chemical and sensory analysis of chlorine dioxide in drinking water. Part II.
R. Devesa, Aigues de Barcelona / Chemistry Laboratory; P. López, Universitat Politecnica de Catalunya UPC; M. Nuñez, M. García-Mendi, Aigües de Barcelona, Agbar; F. Estrany, Universitat Politecnica de Catalunya UPC
Drinking water supply companies have traditionally focused their efforts on providing a product with health guarantees, a safe and clean water. Disinfection has been the main purpose of the water treatment. A broad range of disinfectants and technologies are available. Chlorine dioxide has been increasingly used because of its ability to avoid the formation of trihalometans (THMs), the most common and well known disinfection by-products.The origin of the present work was a taste and odour episode which occurred in the water supply system of the city of Barcelona and was attributed to the use of chlorine dioxide for final disinfection in one of the sources. The study had two main objectives: first, develop an analytical method to analyse low levels of chlorine dioxide in presence of chlorine; and second, estimate the organoleptic properties of chlorine dioxide in order to explain the customer complaints. In part I of the project (1) the behaviour of DPD and Lissamine Green B were evaluated. Now, the results of the experiments with amaranth and chlorophenol red (CPR) are presented. It has been demonstrated the amaranth method does not need the addition of glycine, but on the contrary this agent is very useful in the case of the CPR to avoid the chlorine interference. The behaviour of the two methods has been similar. Good calibration curves are obtained although the slope has a poor reproducibility. The validation of both methods with real water samples has showed that the results are acceptable (accuracy error below 20 %) when the concentration of the interfering species, chlorine, is up to 0.8 – 1 mg/L. With respect to the sensory analysis, two odour experiments were performed: discrimination and preference tests between chlorinated vs. dioxichlorinated waters. In part I, some previous results with an untrained panel were presented. Now, additional data with a joint panel including trained tasters are presented. Chlorine dioxide and chlorine can be effectively discriminated. Overall, chlorine dioxide seems to present a stronger odor, although it is not reported as more unpleasant. The results obtained permitted the odour event to be explained: the change of compound for final disinfection was detected by sensitive consumers. (1) R. Devesa et al. Chemical and sensory analysis of chlorine dioxide in drinking water. SETAC Europe 23 rd Meeting, Glasgow, U.K, May 2013. **Keywords**: chlorine dioxide, chlorine, analysis, water.

EU DEMEAU project: Practical application of in vitro bioassays in water quality assessment
E. Simon, Centre Ecotox / Aquatic Ecotoxicology; M. Schriks, KWR Watercycle Research Institute; H. Besselink, Biodetection Systems BV; A. Hebert, VEOLIA Environnement Recherche et Innovatio / Environment and Health; K.A. Baken, KWR Watercycle Research Institute / CWG; R. van der Oost, Waternet / Onderzoek en Advies; B. van der Burg, Biodetection Systems BV; C. Kienle,
Through various case studies the usability of bioassays to measure combined effects of emerging and unknown water pollutants were demonstrated within the EU funded project "DEMEAU". The presentation i) explains how (*in vitro*) bioassays can provide cost-effective means for safety evaluations of water samples and investigation of activity profile of single chemicals, ii) introduces a selection criteria system that helps to compile a relevant bioassay panel for the effect-based screening of drinking, surface and waste waters, and iii) summarizes the main results and conclusions of the demonstration studies.**The following studies will be presented: <strong>1. Establishment of bioassay trigger values\n**The need for trigger values is internationally acknowledged and within the project a proposal to derive human health related trigger values has been reported. Ecotoxicological trigger values are being currently developed.
2. Selection criteria to assess the suitability of bioassays\nA recent inter-laboratory study described the application of a broad panel of *in vitro* bioassays to waste, recycled, storm, surface and drinking waters. Each type of water showed a characteristic bioanalytical profile with particular groups of toxicity pathways. Since there are numerous bioassays available for these pathways, we prepared a criteria system to assess the suitability of the respective bioassays and selected the most promising techniques for water quality assessment. **3. Bioscreening of Managed Aquifer Recharge (MAR) samples\n**Various types of MAR sources from two sampling campaigns were subjected to screening in the selected bioassay panel for their toxicity profile and investigate the impact of micropollutants present in these samples. The study revealed the importance of endocrine, oxidative stress and photosynthesis inhibition pathways, and showed differences between the samples collected in two sampling campaigns. **4. Ecotoxicological evaluation of wastewater treatment\n**The efficiency of ozonation and various post-treatments to reduce ecotoxicological effects still occurring in the conventionally (biologically) treated wastewater was assessed in this study. The investigations revealed that the ozone treatment resulted in significantly improved water quality in the majority of bioassays as compared to effects measured in the conventionally treated wastewater. In a few assays, partially higher effects after ozonation occurred, but could be removed by suitable post-treatments.

Chrysene and dibenz(a,h)anthracene contamination of surface waters: toxicity assessment using water flea (Daphnia magna)
B. Opeolu, Cape Peninsula University of Technology / Faculty of Applied Sciences; A.A. Awe, CPUT / Chemistry; O.S. Olatunji, O. Fatoki, Cape Peninsula University of Technology / Chemistry
Water constitutes about 73%of the earth's surface and only 3% of this is freshwater resources. The surface freshwater resource available as liquid is about 0.3%. Several studies and reports across disciplines had established the universal importance of freshwater for human and ecological health. This limited resource is being exploited and degraded daily especially in the developing world. Climate change and it global impacts continue to exert greater pressure on freshwater resources. The need to develop analytical methods, assess pollution levels, evaluate ecotoxicological effects and remediate wastewaters for possible reuse is now a necessity more than ever. This study aimed at developing an analytical method for the qualitative and quantitative determination of chrysene and dibenz(a,h)anthracene in surface waters and to assess possible toxicity effects of these compounds on water flea, *Daphnia magna*. A method with good linearity and precision was developed to measure chrysene and dibenz(a,h)anthracene in water and sediment samples. Acute Daphnia toxicity testing ws carried out to assess potential harm of these contaminants to ecological health. Results of method development, environmental water monitoring and effective concentrations (ECs) are presented.

Bioavailability and Toxic Response of Bound PAHs in Natural Organic Matters for Oryzias latipes
Y. XU, Research Center for Eco-Environmental Sciences, Chinese Academy of Sciences / Key Laboratory of Drinking Water Science and Technology; Z. WANG, S. Chen, Research Center for EcoEnvironmental Sciences Chinese Academy of Sciences / State Key Laboratory of Environmental Aquatic Chemistry
This research aims to carry out investigation on bioavailability of PAHs in the present of different NOMs for model animal pelagic Japanese medaka (*Oryzias latipes*). Our previous work has shown that the uptake rate of HOCs in triolein-embedded cellulose acetate membrane (TECAM), a kind of passive sampler, is independent on HA concentrations. Thereby, using TECAMs as a biomimetic tool, combined with biomarkers, the bioavailability of bound PAHs in NOMs to *Oryzias latipes*, as well as the aging effect on PAHs-NOM association and its mechanism was studied. Dissolved humic acid (HA), and four kinds of humins from different sources, were examined in this study as different types of NOMs. The freely dissolved concentrations (C_{free}) of PAHs were estimated by using TECAMs. A bioavailability model as follows was used to describe the bioavailability extent of bound PAHs: $F_{fish} = C_{bioavailable} / (C_{free} + C_{bound}) = (1 + \alpha * K_{OM} * C_{OM}) / (1 + K_{OM} * C_{OM})$, where F_{fish} was used to represent the fraction of bioavailable PAHs, and α is the portion of bioavailable fraction of the bound PAHs. On the basis of the bioavailability model, it was estimated that approximately 20% of HA-bound PAHs contributed to the bioaccumulation in *O. latipes*. However , the bioavailability of PAHs in *O. latipes* was reduced significantly by presence of humins after aging for 32 days. In this condition, the humin-bound PAHs were almost completely unbioavailable, whereas only the freely dissolved fraction can be absorbed by *O. latipes*. The strong affinity between the PAHs and humins after aging blocked the possible bioavailability of bound PAHs, in which the major slow-sorption fraction contributed scarcely to the bioaccumulation. In general, the freely dissolved concentration of PAHs can be used to estimate the bioavailability in most cases, as the NOM-bound fraction of bioavailable PAHs was much smaller.

Multiple stresses in aquatic ecosystems: Assessment of stress response and its consequences in organisms (I)

Knowledge, Assessment, and Management for AQUAtic Biodiversity and Ecosystem Services aCROSS EU policies
A.J. Nogueira, University of Aveiro / Biology; A. Rossi, ACTEON; G. Delacamara, Instituto IMDEA Agua; T. Hein, BOKU; A. Iglesias-Campos, IOC-UNESCO; S. Jähnig, IGB; G. Piet, IMARES; M. Lago, Ecologic Institute
Aquatic ecosystems are rich in biodiversity and home to a diverse array of species

and habitats, providing numerous economic and societal benefits to Europe. Many of these valuable ecosystems are at risk of being irreversibly damaged by human activities and pressures, including pollution, contamination, invasive species, overfishing and climate change. These pressures threaten the sustainability of these ecosystems, their provision of ecosystem services and ultimately human well-being. AQUACROSS seeks to advance the application of ecosystem-based management for aquatic ecosystems in an effort to support the timely achievement of the EU 2020 Biodiversity Strategy and other international conservation targets. In this regard, AQUACROSS aims to develop and test an assessment framework which considers the full array of interactions, including human activities, within aquatic ecosystems. Existing EU policies have been unable to halt and reverse the trend of declining biodiversity of aquatic ecosystems. The current broad policy landscape such as the Water Framework Directive and Marine Strategy Framework Directive means that sustainable management solutions require coordination and cooperation between different policy areas spanning freshwater, coastal and marine ecosystems, in addition to innovative business solutions and public-private engagement. The AQUACROSS project will support the achievement of EU and international biodiversity targets by delivering a consolidated and coherent outlook on EU policy for aquatic ecosystems; increasing knowledge on biodiversity and drivers of aquatic ecosystem change; supporting the management of Natura 2000 sites and invasive alien species; and testing environmental and business models for the provision of ecosystem services that will contribute to ecosystem protection.

Assessing dynamics and stability of River Ecosystems under multiple stressors conditions: Iberian rivers as case study

l. sabater, CSIC-IDAEA / Department of Environmental Chemistry; A. Ginebreda, IDAEA-CSIC / Department of Environmental Chemistry; I. Muñoz, University of Barcelona / Ecology; R. Marcé, ICRA Catalan Institute for Water Research / Resources and Ecosystems; D. Barceló, IDAEA-CSIC / Department of Environmental Chemistry

River ecosystems are complex systems that naturally fluctuate on space and time around a regular pattern or dynamic equilibrium, governed by external environmental conditions. If these are varied up to a threshold, the system may shift towards a new contrasting steady-state or regime. Characterizing the ecosystem stability and predicting the conditions under which such shifts are produced is a challenging task that has become an area of growing interest in the last years [1, 2]. The present work aims at progressing on the understanding of the relationships between the dynamics and stability of Mediterranean River ecosystems and the environmental conditions, taking Iberian Rivers as case study. We also aim at bringing closer modelling and field ecology under a common framework that enables the exploitation and interpretation of field measurements. To do so, we applied a mathematical dynamic model structurally equivalent to the well-known Lotka-Volterra that takes explicitly into account spatial relationships [3]. The model considers both the spatial connection and similarity of biological and other environmental descriptors associated to each river site. Its application provides relevant information regarding questions like the system's stability, transition between states, as well as the interpretation of the longitudinal patterns of the rivers and their evolution according to shifting environmental conditions. By doing so, we will approach modeling and experimental environmental practices under a common framework that facilitates the understanding of ecosystems' behavior as regards to multiple stressors effects. Natural variability of biochemical biomarkers in the macro-zoobenthos: dependence on life stage and environmental factors

L. Scarduelli, University of Milano Bicocca / Earth Environmental Science; R. Giacchini, P. Parenti, University of Milano Bicocca / Department of Earth and Enviromental Science; M. Vighi, IMDEA Water Institute / Earth and Environmental Sciences

Biomarkers have been widely implied in ecotoxicology as indicators of exposure to toxicants. However, the usefulness of biomarkers in ecotoxicology and, in particular, their ability to provide unambiguous and ecologically relevant information on exposure to or effects of stress factors remains controversial. One of the major problems for the use of biomarkers in ecotoxicology is understanding if the measured responses are determined by the effects of stress factors or lie within the natural variability range produced by the effect of environmental parameters. In a previous work, the natural variability of enzymatic levels, measured in some freshwater invertebrate taxa sampled in pristine rivers, was proved to be relevant across both space and time. In this work, the experimental design was improved by considering different life stages of the selected taxa and by including the measure of additional environmental parameters. The work aimed at evaluating the variability of some enzymatic biomarkers measured in freshwater benthic invertebrates collected in pristine alpine streams in order to limit any potential anthropic influence. The experimental design considered: sampling sites in two different rivers; eight sampling dates covering the whole seasonal cycle; four taxonomic groups (Perlidae, Baethidae, Heptageniidae, Hydropsychidae) present in almost all samples; three to four different life stages considered for each taxonomic group; four enzymes: Acetylcholinesterase, Glutathione-S-transferase, Alkaline phosphatase, and Catalase. Biomarkers levels were related to several environmental parameters (temperature, pH, conductivity, oxygen level, nitrogen and phosphate concentrations, metals and metalloids concentrations), to verify any kind of dependence. Data were elaborated using multivariate statistical methods. Natural variability of enzymatic levels was found to be relevant across both space and time. The results of this work proved that great care should be paid when interpreting experiments in which biomarkers levels are measured and compared among sites or dates; further research is needed to understand how the natural variability of biomarkers could be accounted for and managed in ecotoxicological studies.

How do anthropogenic pollutants affect the genetic structure of a model invertebrate freshwater population?

P. Inostroza, Helmholtz Centre for Environmental Research GmbH - UFZ / Effect Directed Analysis; J. Wicht, University of Tuebingen / Institute of Physical and Theoretical Chemistry; H. Norf, Helmholtz Centre for Environmental Research UFZ / River Ecology Aquatic Ecosystems Analysis and Management; W. Brack, Helmholtz Centre for Environmental Research UFZ / EffectDirected Analysis

Organisms are rarely exposed to only one single anthropogenic stressor in the environment, but rather to multiple human-derived threats acting simultaneously. Environmental pollution can modify genetic population structure via ecological bottlenecking, adaptation of species to contaminants, altered gene flow, or increasing mutation rate. Organic micropollutants such as pesticides, biocides, pharmaceuticals, personal-care products, or industrial chemicals are ubiquitous in the aquatic environment and their effects are considered a relatively new and emerging anthropogenic pressure over evolutionary processes. Especially potential effects of pollutants on genetic population structure may be more disruptive regarding ecosystem functioning than individual-level effects. Despite the bunch investigations on genetic variation in wildlife, our understanding about the individual stressor effects on genetic variation is still limited. Recently, there has been an increased interest in integrating environmental chemistry and evolutionary ecotoxicology approaches into the assessment of direct and indirect effects of anthropogenic pressures on populations. To address these challenges the genetic structure of a shredder invertebrate, *Gammarus pulex*, was examined using evolutionary ecotoxicology and body burden approaches. Significant genetic depression was detected and remarkable presence of private/rare alleles occured after first WWTP effuents. These effects occured together with a drastic increase in pollutants together indicating their mutagenic activity. Thus, it is highly probable that mutagenic chemicals emmited by the WWTP have a significant impact on genetic variation of gammarids. Conversely, a slight though significant increase in genetic diversity was detected in a short stretch of the river (~four kilometers) marked by rainwater drainage, the second wastewater treatment plant effluent and a small backflow level upstream the weir. These sampling sites showed a strong significant correlation in RDA analysis performed in order to assess the influence of man-made stressors on genetic diversity and structure. This study provides evidence of direct and indirect effects of anthropogenic pollutants on genetic variation in an invertebrate freshwater population. Clear signal of pollutants-induced genetic changes were determined in the Holtemme River.

Influence of chemical and non-chemical stressors on the macroinvertebrate community composition of the Danube river

A. Rico, Wageningen University / Environmental Risk Assessment Team; P. van den Brink, Alterra and Wageningen University / Aquatic Ecology and Water Quality Management Group; A. Focks, Alterra Wageningen University and Research Centre / Environmental Risk Assessment Team

A key challenge for the evaluation of their impacts of chemical pollution in aquatic ecosystems has been to disentangle their isolated toxic effects caused by water contaminants from those originated by other sources of natural or anthropogenic stress. In this study we developed a method for the evaluation of single and combined effects of chemical pollution on aquatic communities of large rivers. The method was based on the combination of univariate and multivariate statistical techniques including GLMs, PCA, RDA and Variation Partitioning. The method was applied to the database obtained as part of the environmental monitoring campaign performed during 2013 in the Danube river and used in the SOLUTIONS project. The database contained information on the macroinvertebrate community from 55 sampling sites and measurements of more than 300 environmental parameters including hydromorphological conditions, physical river alterations, and basic water quality parameters and contaminants (i.e., pharmaceuticals, pesticides, metals, industrial pollutants, etc). The results of this study indicate that the variation in the invertebrate community is principally explained by the combination of hydromorphological conditions and water contaminants. The most important contaminant groups were pharmaceuticals and basic water quality parameters (e.g. nutrients, DO). Furthermore, a trait-based analysis was performed that indicates correlations between the presence of contaminants and functional characteristics of the invertebrate communities. The results of this study indicate main contaminants, species and biological traits that should be further monitored for the evaluation of the ecological status of the Danube river and serves as reference to other river basins in Europe.

503
Freshwater bivalves detoxification of microcystin-LR and Roundup Flash® differ with species: implications for adaptation?
C. Wiegand, Université de Rennes 1 / UMR CNRS ECOBIO; M. Götze, University of Southern Denmark
Species composition in anthropogenic-impacted environments may depend on the capacity of single species to realise their niches within the pollution scenario. Adaptation can be facilitated via different mechanisms, one of which is the efficiency of detoxification. Many indigenous freshwater mussels species are on a decline, whereas invasive ones proliferate in the same pollution scenario, e.g. in water bodies adjacent to farmlands receiving both, pesticides and fertilizers, which mussels would accumulate by feeding via filtration. One of the most used herbicides worldwide is glyphosate, for its seemingly specific inhibition of the amino acid synthesis in plants through the shikimic acid pathway. Evidence about its harmful effects in non-target organisms is rising, in particular for the commercial formulations. Fertilizers stimulate cyanobacterial blooms, which harm organisms via toxic metabolites. Of these cyanobacterial toxins, microcystin-LR is frequent; it inactivates protein phosphatase of type 1 and 2A, causing cellular malfunctions until death of the organism. Within exposure concentration and duration limits, microcystins can be detoxified via conjugation to glutathione by the glutathione S-transferase (GST) enzymes. This study compares biotransformation of microcystin-LR and the herbicide Roundup Flash® (containing Glyphosate as a.i.) and energy allocated to that in an invasive (*Dreissena polymorpha*) and indigenous mussel species (*U. tumidus* and *U. pictorum*). The invasive *D. polymorpha* detoxified microcystin-LR up to 50 μgL^{-1}*via* the sGST but *U. tumidus'* sGST were rather inhibited in the 7 day exposure. Moreover, GST was hampered after 7 days in both indigenous species by Roundup Flash® and could not increase in the mixed exposure. Thus the detoxification capacity of microcystin-LR was limited in the mixed exposure, which lead to enhanced accumulation of the cyanobacterial toxin. Detoxification and other mending processes consumed energy, however the species drew from differen resources: *D. polymorpha* and *U. tumidus* first used glycogen, and after 7 days of exposure *U. tumidus* but not *D. plymopha* consumed lipids. Contrastingly, *U. pictorum* needed the lipids and thus more energy right from the start. Again, *D. polymorpha* seems to combat the environmental stress with less effort. Different life trait consequences may occur via the energy spent, thus potentially lacking for growth and reproduction, leading to consequences on the population level.

Identification and prioritisation of hazardous pollutants in the aquatic environment - the role of effect-directed analysis, monitoring and modelling (I)

504
A conceptual framework for a solutions-focused management of chemicals
J. Munthe, IVL Swedish Environmental Research Institute Ltd; M. Rahmberg, E. Brorström-Lundén, T. Rydberg, IVL Swedish Environmental Research Institute; L. Posthuma, RIVM / Centre for Sustainability Environment and Health; A. van Wezel, KWR Watercycle Research Institute / Chemical Water Quality and Health; G. Altenburger, UFC Centre for Environmental Research / Bioanalytical Ecotoxicology; D. López Herráez, Helmholtz Centre for Environmental Research UFZ
Risk assessment and prioritisation procedures have in common that they are based on extensive research and evaluation and focus on one chemical substance at a time, in contrast to real world contamination comprising thousands of chemicals. Challenges remain to link the occurrence of chemicals to the status of waters, to identify major chemical stressors including mixtures, and to find solutions for abatement. The project SOLUTIONS will address these challenges. To manage the SOLUTIONS approach, a conceptual framework was developed with four main entry points: **Chemicals, Environment, Abatement and Society** based on needsexpressed by end-users. The entry points are linked by four topics which describe the scientific challenges that will be addressed: Under the activity ***Identify and prioritize hazardous chemicals on different scales***, the aim is to provide a hypothesis on causes and candidate chemicals starting with existing monitoring data and applying innovative approaches for improved monitoring such as target and non-target screening, bioanalytical tools and effect-directed analysis – EDA. Modelling using an integrated 'model train' to link emissions to impacts provides a useful tool to fill data gaps and to extrapolate. The activity ***Selection of abatement options*** is focused on developing guidance on selection of and placement of abatement options. The topic ***Decision support for management of chemical pollution*** is aimed at providing guidance on existing and future policy frameworks. Potentials for synergies will be assessed and gaps in current policies identified e.g. for groups of chemicals or specific sectors in society not or poorly covered by existing legislation. Under the activity ***Predict and prioritize future risks*** the approach is to assess future emissions based on an evaluation of relevant societal scenarios (economy, demography, industry, consumption, energy, agriculture)and how these trends and scenarios may affect use and emissions of chemicals. SOLUTIONS will deliver a number of important products which can be used for the implementation of a sustainable use of chemicals in Europe. The information and experiences will provide the basis for introducing an innovative solutions-focused approach in risk assessment for emerging substances.

Coastal rivers are subject to human pressures often combined with the emission of potentially hazardous organic and inorganic contaminants. In addition, some pollutants in previous decades have accumulated in sediment and can be leached into the water column under certain conditions such as floods. Without ending up at alarming levels in terms of toxicity, many contaminants can impact aquatic wildlife. Traditionally, the most studied pollutants correspond to the priority substances listed in the Framework Directive (WFD) such as pesticides, metals, organometals, PAHs and PCBs. There is however a growing awareness of the occurrence of emerging pollutants for which the elimination processes in wastewater treatment plants are not yet adapted. Among them, the musk compounds for which there is currently no environmental quality standards set by the WFD. Synthetic musks are primarily components of personal care products. Because of their ubiquity and lipophilic properties, some of them are found in aquatic organisms, but few data still exist. The monitoring of priority substances and other pollutants, including new emerging substances, requires the implementation of temporal and spatial trend monitoring programs. The use of integrative matrices (biota and sediments) is strongly recommended to achieve such objectives. Fish are ideal for contaminant monitoring as they accumulate pollutants both from the surrounding water and their prey through processes bioaccumulation and biomagnification. This study aims to investigate the occurrence and concentrations of emerging and priority pollutants in various organs (liver, muscles and gonads) in Atlantic salmon (Salmo salar). We investigate the temporal variations of several chemicals (including organochlorine pesticides, HAPs, PCBs, metals and organometals, synthetic musks) and their metabolisation in salmons caught in the Nivelle river (Southwestern France). Several biophysical parameters are also monitor for each individuals (weight, length, sex, age, percent lipid) as well as ecological parameters (C and N isotopic signatures, otolith chemical signatures, scales fingerprinting) over a 20 years period. This monitoring permits to define status and trends for these contaminants, but this multi-contaminant approach gives also inputs to raise important questions for both science and policy such as where does the contamination come from and how can the situation be resolved?

506
Impact of untreated wastewater on a major European river evaluated with a combination of in vitro bioassays and chemical analysis
M. Koenig, Helmholtz centre for environmental research - UFZ; W. Brack, Helmholtz Centre for Environmental Research UFZ / EffectDirected Analysis; P.A. Neale, Griffith University / Smart Water Research Centre; K. Hilscherova, J. Novak, Masaryk University Faculty of Science RECETOX / RECETOX; M.A. Hashmi, Helmholtz Centre for Environmental Research-UFZ / EffectDirected Analysis; S. Seidensticker, Center for Applied Geosciences; M. Krauss, Helmholtz centre for environmental research - UFZ / Effect Directed Analysis; B.I. Escher, Helmholtz Centre for Environmental Research UFZ / Cell Toxicology
The pollution of river ecosystems by complex mixtures of micropollutants, such as pesticides, pharmaceuticals and industrial chemicals is of concern for ecosystem health and for use as drinking water source. Untreated wastewater is discharged into the River Danube in Novi Sad, Serbia, which triggered the

investigation of the load of micropollutants by chemical and bioanalytical analysis applied to three on-site large volume solid phase extracted water samples from the Danube upstream and downstream of a wastewater discharge point. A battery of *in vitro* cell-based bioassays covering important steps of the cellular toxicity pathway revealed prominent effects on the activation of metabolism (arylhydrocarbon receptor AhR, peroxisome proliferator activated receptor gamma PPARγ), endocrine disruption (estrogen receptor ER, androgen receptor AR) and adaptive stress responses (oxidative stress, inflammation). Of the analyzed 261 compounds 112 were detected at least in one sample. Both chemical and biological analysis revealed the same pattern. The site upstream and 7 km downstream of the discharge had a similar burden of chemicals and effects whereas directly downstream of the wastewater discharge effects and micropollutants' concentrations were increased, particularly those typically associated with wastewater. The detected chemicals could explain 28% of AhR activation, 62% of AR inhibition and 24% of glucocorticogenic inhibition in the water extract directly downstream of the wastewater discharge. Thus the direct wastewater discharge increased the micropollutant load, but the large volume of the receiving stream Danube diluted them within a few kilometers to a status similar to upstream of the discharge. Keywords: bioassay; chemical analysis; Danube; Serbia

Detection of physiological activities of pharmaceuticals in river water: Suggestions to prioritization of pharmaceuticals in research involving environmental monitoring and toxicity testing

M. Ihara, S. Hanamoto, Kyoto University; H. ZHANG; H. Tanaka, Kyoto University

Over recent years, growing numbers of human pharmaceuticals have been detected in effluents of wastewater treatment plants (WWTPs) and river water. Although these are generally found at very low levels (e.g., ng/L to µg/L) in these waters, concern about their potential risks to aquatic species has been raised because they are designed to be biologically active. To determine whether pharmaceuticals in aquatic environments pose risks to aquatic organisms, we must know the extent to which such organisms may be exposed to those pharmaceuticals as determined by the pharmaceuticals' respective modes of action. G protein-coupled receptors (GPCRs) are the largest group of these cell surface receptors in eukaryotes, and participate in various physiological and pathophysiological processes. It is estimated that nearly half of all marketed pharmaceuticals act by binding to GPCRs: for example, antihypertensives, antipsychotics, antidepressants, antiallergenics, and antiasthmatics. In 2012, Inoue et al. developed an *in vitro* transforming growth factor-α (TGFα) shedding assay, in which GPCR activation is measured as ectodomain shedding of a membrane-bound preform of alkaline phosphatase-tagged TGFα and its release into conditioned medium. The TGFα shedding assay can detect not only activation but also inhibition of GPCRs, and is a very simple and rapid tool. In this study, we measured the antagonistic activities of GPCR-acting pharmaceuticals in WWTP effluents, and upstream and downstream of the WWTP outfall in Japan using the TGFα shedding assay. We selected receptors for angiotensin (AT1), dopamine (D2), acetylcholine (M1), histamine (H1), and adrenergic family member (β1). Activities detected in waters were quantified as antagonist equivalent quantities (EQs). Antagonistic activity against AT1, D2, M1,H1, and β1 receptor were detected in the final effluent of WWTP A through two years. Particulaly, antagonisitic activity agaainst AT1 and H1 receptor were strong, up to several µg/L as olmesartan-EQ (µg-OM/L) or diohenhydramine-EQ (µg-DIP/L), respectively. Antagonistic activities against AT1, H1, and M1 receptor in downstream of river were higher than those in upstream due to the effluent from the WWTP A. Based on thse results, we propose that pharmaceuticals antagonistic to AT1, D2, H1, M1 and β1 receptors should be prioritized in future environmental monitoring and toxicity testing.

508

Enhanced Environmental Non-target Screening: Connecting Mass Spectrometry, Background Knowledge, Data Sources and Predictions

E. Schymanski, Eawag Swiss Federal Institute of Aquatic Science / Environmental Chemistry; C. Ruttkies, Leibinz Institute of Plant Biochemistry; N. Munz, Eawag / Environmental Chemistry; J. Schollee, Eawag, Swiss Federal Institute of Aquatic Science and Technology / Environmental Chemistry; M. Stravs, M. Loos, Eawag Swiss Federal Institute of Aquatic Science and Technology; E. Mueller, Helmholtz Centre for Environmental Research UFZ; S. Neumann, Leibniz Institute of Plant Biochemistry IPB / Stress and Developmental Biology; H. Singer, J. Hollender, Eawag / Environmental Chemistry

Non-target screening using high resolution mass spectrometry (HR-MS) is essential to help prioritize and identify the tens of thousands of unknown chemicals detected in complex environmental mixtures, but is also time-consuming and requires compilation of information from a plethora of sources. A high-throughput, consolidated non-target identification workflow for HR-MS was developed within the European project SOLUTIONS. The *in silico* fragmenter MetFrag was expanded to include retention time (RT), reference and patent information, spectral similarity, suspect list screening, element and/or substructure selection and exclusion as well as user-defined scores [1,2]. References and patents provide vital clues for high-use substances, while suspect screening allows candidate retrieval from large compound databases (several million entries) combined with tagging entries in various suspect lists (e.g. STOFF-IDENT [3], NORMAN Suspects[4]). User-defined scores allow e.g. the inclusion of per-substance toxicity predictions relevant for effect-directed analysis (EDA). MetFrag2.2 was evaluated on 1308 merged spectra of 975 environmental reference standards from MassBank, with 71 % ranked correctly in first place using fragmentation, RT and reference/patent information. The workflow in R covers peak-picking to identification with enviPick, enviMass, enviPat, nontarget, RMassBank and ReSOLUTION. A graphical user interface, enviPy, is also available. The workflow was tested on upstream, downstream and effluent samples from three locations in the SOLUTIONS Rhine case study. Masses (159 positive, 137 negative mode) were prioritized for identification using peak picking, componentization (isotope, adduct information) and pattern analysis. Transformation products of common surfactants were clearly formed during treatment and present downstream. Downstream of Muri WWTP, 110 high intensity non-targets were investigated, with 83 suspects from STOFF-IDENT (7602 substances, including REACH) among 72,331 total candidates retrieved from ChemSpider. The top matches for 54 masses are highly promising; confirmation efforts are underway. The workflow greatly expedites high-throughput non-target screening and has huge potential to assist prioritization and EDA. [1] Ruttkies *et al* 2015, J. Cheminformatics, under review [2] http://c-ruttkies.github.io/MetFrag/ [3] http://bb-x-stoffident.hswt.de/ [4] http://www.norman-network.com/?q=node/236

Revisiting the Mutagenicity in River Rhine: Identification of Mutagenic Aromatic Amines

m. muz, UFZ - Helmholtz Centre for Environmental Research / Effect Directed Analysis; D. Cassier, A. Bahlmann, M. Krauss, W. Brack, Helmholtz Centre for Environmental Research UFZ / EffectDirected Analysis

Since the 1970s mutagenic activity was observed in many samples from the lower part of River Rhine and although the mutagenicity of the river decreased by time, the activity is still detectable. The mutagenicity increases significantly with metabolic activation in AMES test and comet assays pointing at the contribution of mutagenic aromatic amines. However to best knowledge of the authors, the responsible compounds still remain unidentified. Thus, the aim of this study is to detect and identify the cause of mutagenicity in River Rhine using effect-directed analysis. Samples were taken at Lobith, Netherlands by an on-site large volume SPE machine using a polymeric sorbent. The extract was fractionated using a semi-preparative C18 column and two-minute fractions were collected. Ames fluctuation assay (Ames II test) was used to assess the mutagenicity with tester strain TA98 and strain YG 1024, which has an increased sensitivity for aromatic amines with metabolic activation. The raw extract showed a significant mutagenicity in the presence of S9 with TA98 and YG1024 at a relative enrichment factor of 250. 10 active fractions were detected with TA98 strains and 5 additional active fractions were observed with YG 1024 strains in the presence of S9. The number of revertants increased significantly with YG1024 strains confirming the contribution of mutagenic aromatic amines. The active fractions were analyzed using an ion trap-Orbitrap hybrid instrument (LTQ Orbitrap XL, Thermo Scientific) in ESI positive ion mode by a previously developed pre-column diagnostic derivatization method to selectively label amines. The overview of the first data evaluation reveals the abundancy of compounds with amino groups in the river. Two compounds, namely, Sotalol a commonly used betablocker and Sulfapyridine an antibacterial agent were confirmed by reference standards. Nortilidine and Bisnortilidine, two metabolites of the opioid painkiller Tilidine were found as the only Metfrag candidates and the parent compound, Tilidine, was confirmed with the MassBank spectra match. Moreover, 5-Methyl-1H-benzotriazole, Lamotrigine, p-toluidine and 1H-benzotriazole(BTA) were also confirmed by MassBank spectra matches. In addition to these compounds, MetFrag candidates point out aminoquinilones and other imidazole containing compounds which are currently being evaluated.

Standards - an essential link between environmental science and regulation

510

A regulatory view on the application of standardised tests

A. Smith, Cefas / Ecotoxicology and Molecular Ecology; H. Walton, C. Askem, M. Kirby, Cefas / Ecotoxicology; B. Rowles, Cefas / OCNS; C. Phillips, Cefas

Cefas acts as the UK Government regulators or advisors to the regulators in a number of Marine fields, and also runs a separate ecotoxicology facility which enables us to view the use of standardised testing from more than one perspective. We discuss how the availability of standardised tests affects the regulator and those involved in submitting reports and testing. A case study is examined where the use of standardised tests allowed the regulator to re-assess data from previous submissions Aspects of standardised tests that allow regulations to operate effectively are discussed. Is it critical for the standardised test to be chosen carefully to represent the area of application. A scientific view and a regulatory view are presented. We present a view of how regulatory roles would be affected in the absence of standardised tests We conclude that standardised testing provides a solid basis for regulatory decisions, though should not be the only information permitted OR requested.

Standards in Environmental Toxicology - Strengths and Weaknesses - Practicality versus Complexity
R. Baudo, Renato Baudo; G. Persoone, Laboratory for Environmental Toxicology and Aquatic Ecology, Ghent University, Ghent, Belgium
The strength of Standards in Ecotoxicology is that the users not only know exactly - but also have to abide by - all the detailed descriptions. The Standards prescribed by national and international organizations for toxicity testing unfortunately often differ - sometimes even to a substantial extent - on many aspects. These differences clearly bear an influence on the outcome of the assays. Several examples of the differences of prescribed standard toxicity test methods will be highlighted with regard to e.g. selection of test species, effect criteria, exposure time, number of test organisms and replicates, validity criteria and data analysis. A major drawback of many Standards is that only little attention has been paid to their practicality/complexity aspects. It is often argued that for the evaluation of the hazards of chemicals - as is e.g. the case for REACH dossiers on chemicals - these "inherent" practicality/complexity aspects have to be coped with. Standard toxicity tests are, however, also needed for application in a regulatory framework for routine toxicity assessment of polluted environments, and practicality and cost problems are in this regard a major point. Independently of Standards, scientists have addressed the former drawbacks by developing "small-scale" toxicity test methods, and the name "microbiotests" was coined in this regard in 1991 by Dr. C. Blaise. Microbiotests must be inexpensive or cost-efficient, generally not labor intensive, have high sample throughput potential, be based on cultures which are easily maintained or maintenance free, require modest laboratory and incubation space, low sample volumes and be precise and reproducible. At the turn of the century, the very first simple, rapid and cost-effective microbiotest (the "bacterial luminescence inhibition assay") was proposed and accepted by the ISO and is now in use worldwide. Extensive research on "stock culture/maintenance free" microbiotests has since then been performed at the Ghent University in Belgium, with test species belonging to different phylogenetic groups (algae, protozoans, rotifers, crustaceans, and plants). Validated by extensive International Interlaboratory Comparisons, several of these microbiotests have been accepted by the ISO and because of their "simplicity and practicality" and their availability in kits, these microbiotests are to date also applied worldwide for research and routine toxicity monitoring.

Implementation of the TRIAD approach for the ecological risk assessment of an old lead mine.
N. Pucheux, INERIS; S. ANDRES, INERIS / Toxicological Ecotoxicological Assessment of chemical Substances; P. Pandard, INERIS; C. GRAND, ADEME
Site specific ecological risk assessment of soil contamination goes with intrinsic difficulties. Obvious ones are heterogeneity of soil properties, landscape, local communities, diversity and ecosystem structure, and contamination nature and pressure. In this context, the International Standard ISO/DIS 19204 "Soil quality – Procedure for site specific ecological risk assessment of soil contamination (Soil quality TRIAD approach)" describes in a general way the application of three combined lines of evidence (chemistry, ecotoxicology and ecology). The TRIAD includes different tiers in which each consecutive tier is increasingly fine-tuned according to the site-specific situation. Data collected on an open pit mine operated during 60 years and which the activities stopped about 100 years ago as been used to evaluate the ease and efficiency in using the different tiers of TRIAD. The pollution pressure still present in the mine is of metallic origin (mainly Pb, Cd, Zn) and 5 areas with different levels of contamination, vegetation and quantites of organic matter in soil were chosen. It was possible to apply the tier one tools on every selected locations. The combined use of chemical concentration in soil (Chemistry), plant screening test (Toxicology) and simple vegetation survey (Ecology) were sufficient to asses the risk on some of the areas. In consequence, some of the expensive and time consuming data collected in these locations were not needed to assess the risk. On other locations, uncertainties were still too great and the implementation of higher tiers was needed. The focus during this applied case was on the outcome of the TRIAD method in order to obtain practicable results according to the complexity of the study. It reveals that for some locations, the use of TRIAD method can save financial and time ressources. The use of the highest tier on particularly complex zones will need additionnal datas, future investigations are planned for the year 2016.

Ecotoxicological assessment of corrosion protection products used on hydraulic steel structures
E. Vermeirssen, Oekotoxzentrum Eawag-EPFL / Aquatic Ecotoxicology; C. Dietschweiler, UMTEC, HSR Hochschule für Technik Rapperswil / Institute of Environmental and Process Engineering UMTEC; B. Ganser, A. Schifferli, Swiss Centre for Applied Ecotoxicology Eawag-EPFL; I. Werner, Swiss Centre for Applied Ecotoxicology / Department of Anatomy Physiology and Cell Biology; M. Burkhardt, UMTEC, HSR Hochschule für Technik Rapperswil
Corrosion protection is applied to extend the lifetime and function of steel components. In our study we conducted market research to establish which corrosion protection products are used in Switzerland. It appeared that epoxy resins have ca. 50% market share. Subsequently, we ran laboratory leaching tests with four products and determined the ecotoxicity of leachates using a suite of bioassays. The bioassays we ran were mainly (draft) ISO standards and one non-standard bioassay (the combined algae test) which has been applied in Switzerland in a regulatory context. However, currently no uniform or internationally adopted scheme is available to evaluate results from bioassays run on leachates from construction materials. For this reason we used a German scheme developed by DIBt (German Centre of Competence for Construction) to evaluate our bioassay results. In future, a scheme may become available through CEN (European Committee for Standardisation). CEN is currently preparing a report that will highlight the potential of bioassays for the evaluation of leachates from construction materials. Four types of epoxy resin based products were obtained and prepared according to instructions of the producers. Resins were directly applied onto glass plates without any primer. Two leaching experiments were performed as 7-day horizontal shaking tests using a volume to surface ratio of 10 L/m^2. Toxicity was observed in all tests and particularly two products showed elevated toxicity. For Product 1, a >1000-fold dilution was required to reduce bacterial bioluminescence inhibition under 20% (a threshold specified in the DIBt scheme). Samples from Product 3 induced large effects in several receptor activation assays. Bisphenol A measurements in these samples clearly linked this compound to the observed endocrine effects. Although worst case scenarios were tested, i.e. short hardening times and low volume to surface ratios, the observed effects often require high leachate dilutions to reduce effect-levels below 20%. The DIBt evaluation scheme proved useful for the ecotoxicological evaluation of the leachates. However, a uniform and internationally standardised and adopted evaluation scheme – covering an extended effect panel – is desirable.
Acknowledgement - The authors thank the Swiss Federal Office for the Environment (FOEN) for financial support and industry partners for providing their products for testing.

Lampi, ExxonMobil Biomedical Sciences, Inc.
It is widely-accepted that it is not the total (solvent-extractable), but only the bioavailable fraction of hydrophobic organic contaminants in sediments that is available for uptake in organisms and responsible for any subsequent effects. In view of proper risk assessment and management of contaminated sediments, several methods for assessing bioavailability have been developed and are being used; however, primarily within the scientific community. Among these methods, passive sampling (i.e., determining freely dissolved concentrations; C_{free}) represents the most widely-used and well-characterized approach. In some regulatory communities, there is aversion to implementing these methods in actual risk assessments, as there is no consensus among scientists on which bioavailability assessment or passive sampling approach is best to use and the variability associated with these methods remains largely unknown. Therefore, the objectives of this international ring test study were (1) to map the state of the art in determining C_{free} with passive sampling (i.e., what is the intra/inter-method/lab variability); (2) to identify the sources of variability by means of dedicated, tiered experiments (including standardizing methods); (3) to provide recommendations and practical guidance (standard protocols); and (4) to increase confidence in the use of passive sampling and advance its use outside of the scientific domain. The ring test was performed by a consortium of 11 labs and included experiments with 14 passive sampler types on three sediments and 25 chemicals (i.e., PAHs and

PCBs). The results demonstrated that standardizing methods significantly decreased the overall inter-lab variability. The resulting variability however still largely exceeded the intra-lab/inter-method variability. By performing all analyses in one laboratory, this difference in part could be explained by the substantial variability introduced through analytical chemistry (i.e., identification, integration, calibration of target chemicals). Overall, the findings of the ring test suggest that passive sampling is fit for implementation in risk assessment and the management of contaminated sediments when following standard protocols.

A focus on research and education tools in environmental toxicology and chemistry

Human activities have altered continental ecosystems worldwide and generated a major environmental crisis. To truly develop integrative ecosystem biology and to assess the consequences of various forcing factors, such as pollutions, we therefore need new approaches and tools that bridge the traditional gap between life and environmental sciences. To deal with that challenge, the infrastructure for Analysis and Experimentation on Ecosystems (AnaEE-France) is an integrated network of the major French experimental, analytical and modeling platforms dedicated to the biological study of continental ecosystems, both aquatic and terrestrial. This infrastructure aims at understanding and predicting ecosystem dynamics under global change. It comprises five complementary nodes offering access to the best experimental facilities and associated biological resources and data: Ecotrons, semi-natural experimental platforms to manipulate terrestrial and aquatic ecosystems, *in natura* sites equipped for large scale and long-term experiments. AnaEE-France also provides shared instruments and analytical platforms dedicated to environmental (micro)-biology. Finally, AnaEE-France provides users with data bases and modeling tools designed to represent ecosystem dynamics and to go further in coupling ecological, agronomical and evolutionary approaches. AnaEE-France offers adequate services to tackle the new challenges of research in ecotoxicology, positioning its various types of platforms in an ecologically advanced ecotoxicology approach. AnaEE-France is a leading international infrastructure and it is pioneering the construction of a European AnaEE infrastructure in the field of ecosystem research. This infrastructure is open to the international community of scientists in the field of continental ecotoxicology.

MOSAIC: a web interface with modelling and statistical tools for ecotoxicology
S. Charles, University Lyon 1 / Laboratory of Biometry and Evolutionnary Biology; M. Delignette-Muller, VetAgro Sup / Laboratory of Biometry and Evolutionnary Biology; G. Kon Kam King, University Lyon 1 / Laboratoire de Biométrie et Biologie Evolutive; P. Ruiz, UMR CNRS 5558; P. Veber, University Lyon 1 / Laboratory of Biometry and Evolutionnary Biology
MOSAIC stands for "*MOdeling and StAtistical tools for ecotoxicology*". In ecotoxicology, bioassays are standardly conducted in order to measure acute or chronic effects of potentially toxic substances on reproduction, growth and/or survival of living animals. MOSAIC is a user-friendly web interface dedicated to the mathematical and statistical modelling of such standard bioassay data. Its simple use makes MOSAIC a turnkey decision-making tool for ecotoxicologists and regulators. Without wasting time on extensive mathematical and statistical technicalities, users are given advanced and innovative methods for a valuable quantitative environmental risk assessment. MOSAIC is available at http://pbil.univ-lyon1.fr/software/mosaic/. Today, MOSAIC offers three operational tools : (i) **MOSAIC_SSD**, a tool dedicated to the species sensitivity distribution (SSD) approach aiming at defining safe levels for toxic compounds in an ecosystem through the calculation of the so-called hazardous concentration for *p*% of the species (*HCp*), even when the toxicity values are censored; (ii) **MOSAIC_repro**, which provides users with a complete statistical analysis of bioassay reproduction data simultaneously accounting for mortality all along the bioassay. Concentration-response models are fitted within a Bayesian framework to provide ECx estimates; (iii) **MOSAIC_surv**, which provides users with a complete statistical analysis of bioassay survival data. A log-logistic model is fitted within a Bayesian framework to provided LCx estimates. This presentation is an overview of MOSAIC features based on illustrative examples as provided within the web interface.

ImpactE: an emerging innovation center in environmental performance of processes, products and ecosystems
A. LUTTMANN, S. COTELLE, LIEC - Université de Lorraine - CNRS; J. Masfaraud, CNRS and University of Lorraine; L. Giamberini, Université de Lorraine, CNRS UMR 7360 / LIEC CNRS UMR; P. Bauda, LIEC - Université de Lorraine - CNRS / LIEC CNRS UMR; F. Thomas, LIEC Université de Lorraine CNRS
The innovation center ImpactE, created in 2015, aims at transferring scientific knowledge and technical skills in ecology, ecotoxicology, microbiology, bio-geochemistry and physico-chemistry, from the laboratory to the industry. The targeted partners are manufacturing industries concerned with the environmental impact of their activities, environmental engineering companies, and companies involved in sustainability development. The activity is presently focused on assisting small and medium size companies to improve their eco-efficiency, and thus to increase their economic health. Therefore we raised co-funding from Municipal and Regional authorities, the French State and Europe. ImpactE offers : Studies to improve environmental performance of manufactured products, taking into account ecotoxicity risk assessment, according to the physical and chemical properties of the products, Studies to reduce the environmental impact of manufacturing, according to sustainability development concepts : waste and sewage management, monitoring of contaminated sites, remediation technologies, Training courses for companies personal in ecology, ecotoxicology, risk assessment, … The ImpactE team provides high level scientific skills acquired by a long time experience in the multi-disciplinary research areas. We also can help our partners to perform funding arrangement of collaborative projects. Keywords : environmental risk assessment ; environmental performance ; research and education tools ; innovation

The NORMAN network's special view on prioritisation of biocides as emerging contaminants
V. Dulio, INERIS; p. von der ohe, German Federal Environment Agency UBA; F. Botta, INERIS; I. IpolyI, EI; H. Ruedel, Fraunhofer IME - Institute for Molecular Biology and Applied Ecology / Environmental Monitoring; J. Slobodnik, Environmental Institute
NORMAN promotes the use of innovative monitoring and assessment tools for identifying the substances of emerging concern most in need of future regulation. The network maintains various databases (e.g. EMPODAT) and has developed a prioritisation scheme specifically designed to deal with "problematic" substances for which knowledge gaps are identified. These tools have been significantly improved in recent years (expansion of EMPODAT database from 1 million to more than 6 million records; a new "ecotox" module to allow systematic collection of ecotoxicity test data from online databases worldwide, plus existing regulatory EQS/PNEC values). The NORMAN list of "frequently discussed" emerging substances contains 862 compounds: among them, 253 are "new" substances which have been added to the previous list from 2013, whereas 100 substances are now labelled as "former NORMAN" emerging substances. As regards biocides, the list contains 151 active substances of emerging concern that are still in use, under review or formerly used and 12 compounds (e.g., cybutryne, cypermetryne, dichlorvos, etc.) that are still listed for data collection but labelled as "former NORMAN" compounds. The NORMAN prioritisation scheme helps to identify some compounds which evidently need control / mitigation measures (e.g., deltamethrine, terbutryn, imidaclopride, carbendazim, triclosan). Moreover, it is possible to cite substances for which additional monitoring data would be needed,such as e.g., fenoxycarb and tolylfluanid with a potential risk of exceedance of the PNEC. Cyfluthrin and permethrin were identified as substances for which analytical performance should be improved (target: achieve LOQ < PNEC) and N,N-diethyltoluamide and propiconazole appear as substances already sufficiently monitored and for which no evidence of risk was identified. Biocides are active substances emitted into our environment which are definitely to be regarded as substances of emerging concern. EMPODAT confirms that biocides are still insufficiently covered in monitoring programmes: data are available for 70% of the compounds that are also used as plant protection products, but only 15% of the compounds used solely as biocides have monitoring data in the database. Access to the latest information on emerging pollutants, with an overview of benchmark values on their occurrence across Europe would certainly be of a major importance for risk assessors.

Master Ecophysiology Ecotoxicology Université Pierre et Marie Curie - Sorbonne Universités
D. SIAUSSAT, Institute of Ecology and Environmental Sciences / Department of Sensory Ecology
The EPET specialty is a new specialty at the University Pierre et Marie Curie (UPMC) that is part of the important scientific restructuring implemented in recent years at UPMC around environmental sciences. This specialty complete the other master programs by developing more particularly environmental issues at the organism levels. Lessons taught by various specialists have the objectives to train students to: - The complexity of the relationships between organisms and their environment - The response of microorganisms, animals and plants to changes in their environment (land and water), and impact on ecosystems. - The acclimation mechanisms and detoxification / resistance organizations: plastic phenotype expression, epigenetic ... - The different approaches used in an environmental context and laboratory molecular biology, biochemistry, physiology, ethology, ... - Abiotic stresses (temperature, light, salinity, pollutants ...) and biotic (food availability, parasitism, symbiosis, ...) in a context of human impact and climate change. - The importance of the entire organization in solving environmental, industrial and management / protection of species and ecosystems in the framework of sustainable development. This training involves many researchers developing ecophysiology and / or ecotoxicology research in different sites of UPMC ... ... on different models (micro-organisms, plants and animals) living in aquatic and terrestrial environments. ... with the involment of various organizations and companies working in the field

PROFETIA: Open and Online Training Program in Aquatic Ecotoxicology
L. Parent, Télé-université / UER Science et TEchnologie; S. Betoulle, URCA / UMRI SEBIO; M. Fournier, INRS-Institut Armand Frappier / ISMERUQAR; M. AUFFRET, IUEM / LEMAR UMR
ECOBIM, the international research network in aquatic ecotoxicology was initiated in 2001 by researchers from Quebec (Canada) and France, who shared projects research in aquatic ecotoxicology. While several researchers from countries in Europe, Africa and the Americas participated in the annual meetings, it seemed important to share their teachings to promote transfer of knowledge, harmonizing approaches and methods, and to supplement courses with notions sometimes absent. It was proposed to create a training program that understand different credited modules consisting of digital educational resources available online, as well as methodological harmonization workshops offered in presence at the annual meetings of ÉcoBim. This training program that would be offered to the Master and doctoral level, and initial training or continuous would be the scientific know-how of the ÉcoBIM researchers. This strategic partnership in the field teaching involves the design of educational tools in aquatic ecotoxicology. The PROFECIA project, its objectives and its implementation will be presented.

Advances in Social Life Cycle Assessment and Life Cycle-based Sustainability Assessment

521
Data quality management in Social LCA studies
A. Ciroth; F. Eisfeldt, GreenDelta
Typically, many different information sources are consulted for a social LCA case study, from surveys to company information to public sources of various origins. As social data can change rather quickly, and since several sources can contribute, following a triangulation approach, to a final data point used in a study, an assessment and effective handling of the data quality of social information is important for social LCA. This holds both for social LCA case studies and for generic databases used for them. Understanding the data quality is important especially if the study is used for decision support. An approach for addressing data quality for social LCA studies is presented. The approach uses a specific pedigree matrix to evaluate the quality by 5 different indicators, following evaluation scores from 1 to 5. This matrix is implemented in an LCA software (openLCA), and it is also supported by the social LCA database PSILCA. In a case study on latex products, it is shown how both together support the management of data quality for social LCA in decision support, to detect e.g. whether hot spots appear in the case study to some extent because of weak data quality, or whether hot spots call for immediate action because they are based on reliable information. And, of course, also vice versa, there may be cases where hot spots are not visible because the available information is weak, hiding hot spots.

522
A methodology for social impact assessment of nano-enabled products
v. subramanian, Ca Foscari University of Venice / Dept of Environmental Sciences Informatics and Statistics; E. Semenzin, Ca Foscari University of Venice / Department of Environmental Sciences Informatics and Statistics; A. Zabeo; D. Hristozov, Ca Foscari University of Venice; I. Malsch, Malsch TechnoValuation; P. Saling, BASF SE / Sustainability Strategy; T. van Harmelen, T. Ligthart, TNO; A. Marcomini, University of Venice / Department of Environmental Sciences Informatics and Statistics
It is widely agreed that the entire Life Cycle of nano-enabled products is the appropriate unit of analysis to consider its sustainability aspects, including its social impacts. However, there is limited information on which social impacts are relevant for nano-enabled products, and a methodology to monitor them is lacking. In the EU SUN (Sustainable Nanotechnology) project a quantitative methodology based on Social Life Cycle Assessment (s-LCA) and Multi-Criteria Decision Analysis (MCDA) is proposed to assess the social impacts of nano-enabled products through their Life Cycle. The s-LCA conceptual scheme (i.e. impacts and indicators for different stakeholders) is developed through an appraisal of literature on social impacts of products and Ethical Legal and Social Impacts of nanotechnology, and comprises of nine impacts each for workers, consumers and community and six impacts for value chain actors. Out of them, five indicators associated with impacts of nano-enabled products, with two impacts in Worker category (Professional training and Non-fatal accidents) and three impacts in Community category (Education, Employment, Research and Development expenditure), were identified as relevant to compare nano-enabled products with similar functionality or nano-enabled product with their conventional counterpart. The indicators are organized within a conceptual scheme comprising of benefits (Education, Employment and Professional training) and costs (Research and Development expenditure and Non-fatal accidents). A quantitative MCDA methodology is proposed and applied to a case study that compares the social impacts of two nanotechnology applications. One advantage of using MCDA with s-LCA is that qualitative stakeholder preferences on indicators can be combined with quantitative indicator scores. The gaps to be addressed to expand the future development of methodologies to assess social impacts of nano-enabled products are also considered in the work.

523
Exploring correlation between spatial distribution of fertilizers emissions and social disfavour indicators: a case study in Luxembourg
S. BOURRELLY, Université Lyon III Jean Moulin; A. Marvuglia, Luxembourg Institute of Science and Technology (LIST) / Resource Centre for Environmental Technologies CRTEResource Centre for Environmental Technologies CRTE
This work is the first step of a research aiming at a coupling of health geography and LCA to: 1) calculate and map the impacts of agricultural practices on ecosystems and 2) find their correlation with human factors that we call *social disfavour indicators* (such as low incomes, high distance from hospitals, low level of education, high rate of unemployment, etc.). The aim of the analysis is exploring the existence of a statistically relevant correlation between ecosystems' damages and human health, and providing a representation of this correlation at a fine spatial scale (at the level of the territory of single communes). In this respect, LCA can nicely complement health geography by providing spatial information (to calculate emissions and translate them into potential impacts) and health geography can provide to LCA powerful computational techniques to evaluate spatial correlations. In this presentation we show the application of a clustering methodology very commonly used in computational geography in order to groups communes by classes of criticality with respect to risk of environmental contamination and their correlation with variables of social disfavour. The presentation also introduces the limits of this method and proposes a possible enhancement of the methodology.

524
Life cycle sustainability assessment for agricultural holdings: integrating environmental, economic and social aspects
A. Roesch, Agroscope Reckenholz-Tänikon Research Station ART / Agroscope; T. Nemecek, G. Gaillard, Agroscope / Institute for Sustainability Sciences ISS
Despite the widespread acceptance of the 'three-pillar' model for sustainability – environmental, social and economic – there is still a serious lack of technically and practically feasible data-collection solutions for conducting a social life-cycle assessment (SLCA) and life-cycle costing (LCC) for a large sample of agricultural holdings. Despite extensive research there is still a considerable lack of methods for a comprehensive assessment of the sustainability at the farm level as many of them suffer from gaps in the conceptual framework and the thematic completeness. For these reasons, Agroscope has recently completed a project aiming at developing a scientifically sound set of indicators covering the most relevant aspects of sustainability in life-cycle thinking. This includes a comprehensive evaluation of the following impacts on sustainability: (i) resource use demand, (ii) global warming, (iii) eutrophication and acidification, (iv) ecotoxicity, (v) biodiversity, (vi) soil quality, (vii) economic sustainability, and (viii) social sustainability. A special focus was placed on the following aspects, which are highly relevant to agriculture: (i) ecotoxicity, biodiversity and soil quality, (ii) social sustainability, including animal welfare, physical and mental workload, and the aesthetic value of the agricultural landscape, and (iii) a set of economic indicators aiming to reflect the long-term economic viability of agricultural holdings. For the social dimension of sustainability, a detailed questionnaire was designed in order to address all dimensions of social responsibility, including interactions with business partners and the surrounding community, as well as with farm workers. Subjective social indicators were included in the indicator set with a view to supplementing the objectively derived indicators with perception-based information. Furthermore, a sophisticated

indicator for the workload of both the farming family and the employees was developed. The landscape quality will be assessed by the diversity Shannon index based on preference rating scores for typical agricultural landscape elements. Animal welfare will be included by a pragmatic approach based on a credit point system. The implementation of an efficient data collection process will be tested in a follow-up project based on a small sample of farms, with the mid-term objective to extend the sample on a substantial part of the Swiss farming sector.

525
Life cycle sustainability analysis - a procedure and a case study
T. Ekvall, H. Ljungkvist, IVL Swedish Environmental Research Institute; A.F. Sandvall, E.O. Ahlgren, Chalmers University of Technology
This presentation aims to contribute to the development and demonstration of an operational approach to life cycle sustainability analysis (LCSA). This approach originates from the framework developed within the EU project CALCAS. The framework is different from the life cycle sustainability assessment outlined by Klöpffer in that it not only broadens the scope of life cycle assessment (LCA) to include economic and social aspects, but also allows for deepening of the analysis. It is also different in that it does not predefine the LCSA to be the sum of LCA, life cycle costing (LCC) and social LCA. Instead, the sustainability indicators, the systems investigated and the methods used for the analysis are all decided case by case. Our LCSA approach has two distinct features: 1. the case-specific research questions are defined in a participatory procedure that involves an Open Space workshop; 2. the analyses are carried through by a network of researchers and experts. A network is necessary because the research questions are not known in advance. We applied the approach in a sustainability assessment of a 50 km pipeline for transfer of residual heat from industries to a large district-heating system. The LCSA included 14 research questions on economic, environmental and social aspects. The results indicate that the pipeline is likely to reduce the total costs of the system, but the expected profit is rather small and uncertain, and it is difficult to find a market model that ensures eveyone a share of this profit. The environmental benefits of the pipeline are highly dependent on what electricity production increases when the use of residual heat in the DH systems reduces the combined heat and power production in these systems. The pipeline is likely to have no significant impact on the employment and a somewhat negative impact on the land owners. In conclusion, our LCSA approach proved to be operational. The Open Space format for workshops can generate a good basis for the research questions; however, care must be taken to ensure a balanced participation at the workshop, and complementary research questions might have to be added after the workshop. We found that an LCSA that is the sum of LCA, LCC and social LCA does not cover all sustainability aspects that stakeholders can consider important. We also found that the sustainability of a pipeline for residual heat is uncertain in this specific system and in the time frame investigated.

Exploring links between the biodegradation of chemical contaminants, the metabolic capability of microbial communities and environmental variables

526
Biodegradation of volatile hydrocarbons in five surface waters tested as composed mixtures in the μg/L range
H. Birch, DTU Environment / Department of Environmental Engineering; R. Hammershøj, P. Mayer, Technical University of Denmark / Department of Environmental Engineering
Biodegradation is an important removal process for many chemicals that are released to the environment. High quality experimental data are thus needed for the development and verification of biodegradation models. In biodegradation tests as well as in the environment, the microbial population is not controlled, and therefore a source of variability. In this study the variability of biodegradation in five different surface waters in Denmark with different characteristics regarding pre-exposure to petroleum hydrocarbons was investigated. The study was conducted with a composed mixture of 9 hydrocarbons that were all within a narrow carbon number range (9-12 C) but diverse in molecular structure. The 9 tested compounds were characterized by low aqueous solubilities and even lower environmental concentrations, and all experiments were thus conduted well below solubility and in the μg/L range. The test method was based on OECD 309 but adapted for hydrophobic and volatile test chemicals. Stock solution of ~ 1/100 of the solubility for each chemical was prepared by partitioning based dosing from a loaded silicone polymer. 20 mL test systems were then prepared using 13.5 mL of the surface water innoculum and 1.5 mL stock solution. Test systems were incubated at 20 °C for a maximum of 28 days on a roller and at fixed time intervals three replicate test systems and abiotic controls were analyzed on GC-MS using fully automated Head Space Solid Phase Micro Extraction (HS-SPME). Primary biodegradation (substrate depletion) was determined based on the HS-SPME measurements relative to the abiotic controls. The general order of biodegradation in the five surface waters was n-Decane > Bicyclohexyl > 1,2,4-trimethylbenzene ~ Biphenyl ~ Naphthalene ~ Tetralin > 2,3-Dimethylheptane > Decalin > 1,3,5-Trimethylcyclohexane. Lag phases were between 0 and 8 days. The half-lives were similar in four of the surface water samples and lower than predicted using the BioHCwin model. However, 1,3,5-Trimethylcyclohexane had a predicted half-life of 3.5 days but was only degraded in one sample after all other test chemicals were degraded. In the fifth sample from the clean lake half of the half-lives were higher and half lower than predicted in BioHCwin.

527
Exploring biotransformation of micropollutants in phytoplankton species: overview and influencing factors
M.A. Stravs, Eawag, Swiss Federal Institute of Aquatic Science and Technology / Environmental Chemistry; F. Pomati, Eawag, Swiss Federal Institute of Aquatic Science and Technology / Aquatic Ecology; J. Hollender, Eawag / Environmental Chemistry
The role of phytoplankton in the biotransformation of micropollutants in surface water is largely unstudied; however recent studies indicate a potential role of phytoplankton organisms in the degradation of crop protection products. With three model species (*Microcystis aeruginosa* and *Synechococcus sp*., cyanobacteria, and *Chlamydomonas reinhardtii*, a green alga), we investigated biotransformation reactions of a set of 24 micropollutants, composed from strobilurin and azole fungicides representing diffuse source pollutants and pharmaceuticals representing point source pollutants. Among the reactions observed were hydrolysis of esters, dealkylations, methylations, deaminations and dehydrations, as well as some amino acid conjugations. Biotransformation activity was apparently not sensitive to the presence of low-concentration chemical stressors, however factors like pH and cell density effected some transformation rates. Selected reaction pathways, in particular associated with *Chlamydomonas* in single-strain experiments, could be observed also in experiments with phytoplankton communites sampled from a lake. The study provides a general overview over biotransformation reactions present in phytoplankton species and influence of experimental or environmental conditions.

Glyphosate is biodegraded via two pathways in soil and water-sediment systems - a stable isotope co-labelling approach
K. Nowak, RWTH Aachen University / Institute for Environmental Research Biology V; S. Wang, Helmholtz Centre for Environmental Research UFZ / Dept of Environmental Biotechnology; A. Miltner, Helmholtz Centre for Environmental Research UFZ / Department of Environmental Biotechnology; A. Schaeffer, RWTH Aachen University / Institute for Environmental Research; M. Kästner, Helmholtz centre for environmental research - UFZ / Department of Environmental Biotechnology
Glyphosate and its metabolite aminomethylphosphonic acid (AMPA) are frequently detected in soil and freshwater sedimentary environments, but there are no comprehensive studies on glyphosate behaviour in these systems. Microorganisms can use C and N from a pesticide to synthesize their biomass compounds, e.g. amino acids (AA) and fatty acids (FA). The extraction of known microbial biomarkers from soil or sediment after addition of C and N isotope tracer allows an estimation of microbial activity in the transformation of pesticide. We investigated the degradation pathways of glyphosate with the particular focus on the metabolic incorporation of the isotope label into AA, FA and their fate over time. An agricultural soil and water-sediment were incubated with co-labelled glyphosate ($^{13}C_3{}^{15}N$-glyphosate) in the dark and at constant temperature (20°C). $^{13}C_3{}^{15}N$-glyphosate was used to determine its turnover mass balance over a period of 80 days. Soil and sediment samples at the respective sampling date were analysed for the amount and the isotopic composition of AA, FA, CO_2, solvent-extractable parent compound and metabolites and total NER. In the water-sediment system, 55.7 % of ^{13}C of glyphosate was ultimately mineralised, whereas the mineralisation in the water system (without sediment) was low, reaching only 2.4 % of ^{13}C of glyphosate equivalents. Glyphosate was mineralised in the soil more rapidly and at the end labelled CO_2 constituted about 73% of $^{13}C_3$-glyphosate equivalents. A rapid increase in $^{13}C^{15}N$-AMPA after 10 days was noted in water-sediment system and these transformation products ultimately constituted 26.2 % of the $^{13}C_3$-glyphosate and 78.5 % of the ^{15}N-glyphosate equivalents. In contrast, in the soil, $^{13}C^{15}N$-AMPA increased initially but after 20 days decreased slowly reaching ultimately 12.3 % of the $^{13}C_3$-glyphosate and 39.6 % of the ^{15}N-glyphosate equivalents. Initially, glyphosate was biodegraded via the sarcosine pathway related to microbial growth, as shown by co-labelled $^{13}C^{15}N$-glycine. Later, degradation via AMPA dominated under starvation conditions, as shown by the contents of ^{13}C-glycine. The presented data provide the first evidence of the utilization of glyphosate as a C and N source and highlight the relevance of both the sarcosine and the AMPA pathways in the water-sediment and soil system.

529
NfsA-FRP nitroreductase enzyme family: a new tool to link biotransformation pathways and environmental contamination by mesotrione, a beta-triketone herbicide
L. CARLES, CNRS-Clermont Université, Université Blaise Pascal; P. BESSE-HOGGAN, CNRS-Clermont Université, Université Blaise Pascal / Institut de Chimie de ClermontFerrand; M. JOLY, CNRS-Clermont Université,

Université Blaise Pascal / Laboratoire Microorganismes Génome et Environnement; A. VIGOUROUX, S. MORERA, CNRS-CEA-Univ. Paris-Sud, Université Paris-Saclay / Institute for Integrative Biology of the Cell; I. BATISSON, CNRS-Clermont Université, Université Blaise Pascal / Laboratoire Microorganismes Génome et Environnement
Mesotrione is a β-triketone herbicide commonly used on corn since 2003. The fate and persistence of this compound in the environment is characterized by a relatively high mobility and bioavailability. Two major metabolites resulting from biotransformation are commonly found in soil: 4-methylsulfonyl-2-nitrobenzoic acid (MNBA) and 2-amino-4-methylsulfonyl benzoic acid (AMBA). Several mesotrione-transforming bacterial strains have been isolated from various environments such as farmland and cloud water. Although these strains belong to different genera, the mesotrione transformation pathways are well conserved and lead to MNBA and AMBA, as observed in soil. A mesotrione-transforming strain, *Bacillus megaterium* Mes11, isolated from farmland showing mesotrione transformation capacities [1] was used as a model strain to characterize its biotransformation pathways. Complementary chemical, biochemical and biological approaches were used to identify the biotransformation products of mesotrione and the enzymes involved in the first step of biotransformation. A proteomic study on Mes11 revealed a network of differential expressed proteins being linked to nitroreductase (NR) enzymes [2]. These results were consistent with the chemical structures of metabolites, strongly suggesting the involvement of a NR in the transformation of mesotrione into AMBA. A screening of Mes11 NR revealed two enzymes (NfrA1 and NfrA2) capable of reducing the nitro group of mesotrione. Both purified Mes11 NR were structurally and functionally characterized. They belong to the NfsA-FRP family of Nitro FMN reductases, previously shown as having activity on different nitro-aromatic compounds. Interestingly, members of the NfsA-FRP family have also been identified in other mesotrione-transforming strains, suggesting a key role of these enzymes for mesotrione transformation in various environments. The broad range of temperature and pH determined for Mes11 NR activities strengthened this hypothesis. This study constitutes the first identification of enzymes involved in mesotrione biotransformation. These enzymes (or the corresponding genes) may be used as biomarkers to predict natural attenuation of mesotrione in the environment and to assess potential contamination by the parent molecule and/or metabolites. NfsA-FRP NR could also be used in bioremediation processes or in the development of *in situ* biosensors for detection of nitro-aromatic compounds.

Effects of Solids Retention Time on Micropollutant Biotransformation Rates and Pathways in Activated Sludge
S. Achermann, Eawag
An important parameter in wastewater treatment is the solids retention time (SRT), defined as the time during which the suspended biomass, on average, is retained in the system. Since slow-growing prokaryotes such as nitrifying bacteria can only build up significant populations at higher sludge ages, the SRT significantly influences the microbial community composition. Several research groups have reported an enhanced micropollutant removal capacity of different compounds at higher SRTs, e.g., [1], the underlying causes however are still unclear. In this study, a series of six sequencing batch reactors (SBRs) was operated at SRTs between one and fifteen days. With batch experiments, the biotransformation rates (k_{bio}) were estimated from the concentration-time series, and transformation product formation was investigated for compounds belonging to specific chemical classes of interest. Removal of ammonia and the formation of nitrate were higher in the SBRs run at higher SRT. The estimated biotransformation rate constants from the batch experiment were normalized for each compound and when these normalized rate constants were averaged across all compounds for each reactor, a strong correlation between the average rate constant in each reactor and SRT was observed. However, we found that individual compounds showed strongly deviating behavior from this average trend. A clustering of compounds according to the trends of the transformation rate constants with SRT was therefore sought. When doing so, we observed different trends amongst the compounds, three of which correlated well with nitrification rate, oxygen uptake rate and SRT, respectively. For three of the clusters we identified groups of chemically similar compounds that (mostly) showed the same trend. The group of p-aminobenzenesulfonamides, for instance, showed a slight decrease of transformation rate constants with SRT, highlighting the importance of understanding the influence of SRT at the level of compound classes. In a follow-up analysis, we will then attempt to link the observed trends for types of biotransformation reactions with microbial community features, including taxonomic richness, composition and gene expression of relevant functional genes. Preliminary biodegradation studies in water of commercial homo-polymer polycaprolactone by MALDI-TOF IMAGING technique to be used as probe of river metabolism
D. Rivas, CSICIDAEA / Enviromental Chemistry
MALDI IMAGING MS consists on the use of matrix-assisted laser desorption ionization as a mass spectrometry imaging technique. The sample is scanned in two dimensions at a preselected spatial resolution while the mass spectrum is recorded. Advantages, like measuring the distribution of a large amount of analytes at one time without destroying the sample, make it a useful method in solid-surface study. The present study aims at developing an analytical quantitative method for the study of biodegradation of a commercial homo-polymer to be further used as a probe for the evaluation of the so called "river metabolism". Polycaprolactone (average MW=1250) was selected as suitable candidate polymer. MALDI-ToF imaging experimental conditions were optimized. The method was tested in the lab using under different environmental conditions. Progress of biodegradation after several days of exposure was reflected on the changes in the mass spectra corresponding to variations in the chain length distribution pattern. Results were investigated using different image processing tools

Mechanistic toxicology of engineered nanomaterials: state of the art and future perspectives (II)

Toxicity exerted by AgNPs in OECD and LUFA 2.3 soils: From molecular to organism level responses in Eisenia fetida earthworms
N. Garcia-Velasco, A. Peña, B. Zaldibar, M. Soto Lopez, University of the Basque Country UPV-EHU / Department of Zoology and Animal Cell Biology
Over 400 consumer products contain AgNPs (24% of the total products containing nanomaterials; e.g., detergents, paints, printer inks and textiles), which are also used in biomedical devices and water treatments due to their antimicrobial properties. Since the number of applications is widely increasing the release of AgNPs into different environmental compartments is already occurring, thus, the concern about the still scarcely known hazards of nanosized materials to environmental health has considerably grown. To date, the potential risk of AgNPs has been mainly studied in aquatic environments, while their effects on soils are less investigated despite the great complexity of soil matrix and the potential interactions of soil components with pollutants. These components (O.M, cations, soil colloids and water) together with the soil type varying pH and ionic strength factors, may affect the behavior of NPs, with particular effect on the aggregation and subsequent effect on their toxicity in organisms inhabiting soils. *Eisenia fetida* earthworms have been widely used as model organisms for soil health assessment due to their capacity to accumulate pollutants and their quick and measurable responses at different levels of biological complexity. Hence, the aim of this work was to compare the toxicity exerted by AgNPs in two widely used standard soils through molecular, biochemical and cellular responses measured in this earthworm. With such a purpose, *E. fetida* earthworms were maintained in OECD artificial soil (10% O.M) and in LUFA 2.3 natural standard soil (1.62% O.M) spiked with environmentally relevant and high but sublethal concentrations of AgNPs (0, 0.05 and 50 mg AgNPs/Kg). After 3 and 14 d of exposure, Ag accumulation, weight loss, coelomocyte number and viability, metallothionein (MT) levels and catalase (CAT) activity, damage in DNA and MT transcription levels were recorded. Results indicated that earthworms exposed to 50 mg AgNPs/Kg presented the highest weight loss, affection on coelomocyte parameters, an increase in MT levels and CAT activity and DNA damage in both soil types, although these effects were enhanced in earthworms maintained in LUFA 2.3, where mortality (7,5-10%) was also observed. It can be concluded that apart from the intrinsic properties of NPs (shape, size, surface chemical and charge) the characteristics of the exposure scenario (i.e. soil type, pH, O.M) are to be considered when assessing toxicity of AgNPs in soil.

533
Toxicity of Pristine and Aged Coated Copper Oxide Engineered Nanomaterials (CuO ENMs) to the Earthworm E. fetida
K. Tatsi, Plymouth University; T. Hutchinson, School of Biological Sciences, Plymouth University / School of Biological Sciences; B. Shaw, School of Biological Sciences; N. Ehrlich, Technical University of Denmark / National Food Institute; M. Correia, Technical University of Denmark DTU / National Food Institute; R.D. Handy, Plymouth University / School of Biological Sciences
Many engineered nanomaterials (ENMs) are coated to enhance their technical properties, but these coatings may also change their environmental fate and potential toxicity. There is currently little knowledge on the biological effects of aged nanomaterials and therefore two experiments were conducted to assess the differences in the effects of different coatings on ENMs to adult earthworms (*E. fetida*) as pristine ENMs and after 1 year of aging based on OECD TG 207. In both studies, worms were exposed for 14 d to negatively/positively charged, organic coated or uncoated (core) CuO ENMs (indicative size range of primary particles 10-20 nm) at nominal concentrations of 200 and 1000 mg Cu kg^{-1} with a comparison to ionic copper (200 mg Cu kg^{-1},as $CuSO_4$) in standard Lufa 2.2 soil. Survival, weight of earthworms and tissue metal concentrations (after a 24 h depuration period) were assessed at 7 and 14 d in each experiment. Biochemical endpoints were also analysed in worms from both experiments at 14 d to enable the determination of oxidative and osmoregulatory stress. Total Cu concentrations and pH (in 2:1 soil:water mixture) were measured in soils at 0, 14 d and after 1

year of aging. There were no statistically significant differences between soil pH in all treatments (ANOVA, $P > 0.05$) so the data were pooled and the pH was 5.3 ± 0.2 and 5.2 ± 0.3 (mean ± SD, $n = 40$) at the end of the pristine and aged soil experiment, respectively. After 14 d, control group survival was 100 % in both pristine and aged soil experiments. In worms exposed to 1000 mg Cu kg^{-1} CuO ENMs, survival was only 50 and 40 % in the negatively and positively charged CuO ENM treatments, respectively, while in aged soil experiment only exposure to positively charged CuO ENMs resulted in a 30 % survival. In both pristine and aged soil experiments, body wet weights were significantly reduced (ANOVA, $P < 0.05$) between 10 and 30 % and 30 and 50 % in all low and high Cu treatments, respectively, compared to controls. Total Cu in earthworms exposed to 200 mg Cu kg^{-1} and 1000 mg Cu kg^{-1} ranged from 0.02 – 0.14 and 0.05 to 0.3 mg Cu kg^{-1} dw, respectively, at the end of the pristine soil experiment, analysis of the worms from the aged soil experiment is in progress. Early findings indicate aged ENMs are less toxic to earthworms than the pristine ENMs. The research is funded by EU FP-7 NANOSOLUTIONS Project, Grant Agreement No.309329.

Toxicity of silver nanoparticles to soil organisms: an integrated in vitro- in vivo approach

S. Makama, Alterra Wageningen University and Research Centre / ToxicologyAnimal Ecology; S. Kloet, Wageningen University; T. De Boer, Vrije Universiteit; J. Piella, Catalan Institute of Nanoscience and Nanotechnology ICN2 / Inorganic Nanoparticles; H. vanden Berg, Wageningen University Research Centre / Toxicology Department; D. Roelofs, Vrije Universiteit Amsterdam / Department of Ecological Science; V. Puntes, Institut Català de Recerca i Estudis Avançats ICREA / Experimental Science and Mathematics; K. van Gestel, VU University Amsterdam / Ecological Science; I.M. Rietjens, Wageningen University / Division of Toxicology; N. van den Brink, Wageningen University / Dept of Toxicology

As engineered nanoparticles (ENPs) continue to find increasing applications in society, elucidation of their potential to pose environmental risks is urgent. We investigated the effects of size (20, 35 and 50 nm) as well as surface coating/charges (chitosan/positive CHIT; bovine serum albumin/negative BSA, and polyvinylpyrrolidone-55/neutral PVP-55) on the toxicity of silver nanoparticles (AgNPs) in *in vivo* (*Lumbricus rubellus*) and *in vitro* (RAW 264.7 cell line) models. A 28-day sub-chronic exposure in soil spiked with varying concentrations (0 – 250 mg/kg soil) revealed highest uptake of AgNP_BSA by earthworms (body burdens 50 – 100 mg/kg BW), with already high uptake after only 72h. The number of cocoons produced was most affected by negatively charged AgNP_BSA particles. Similarly, results from cellular *in vitro* tests indicate the highest induction of TNFα with AgNP_BSA (70x higher than control). Significant *in vitro* ROS induction was only observed for the 20nm positively chitosan coated particles. Cytotoxicity tests showed no significant differences between the different types of AgNPs. Gene expression profiling using whole tissues of earthworms exposed to the different AgNPs was conducted and analyses are on-going. Early indications of gene alterations suggest the AgNP_BSA to be more effective. The present study provides further evidence of the influence of ENP properties in driving their bioaccumulation and toxicity.

Trophic transfer of engineered nanoparticles in terrestrial food chains

J.C. White, Connecticut Agricultural Experiment Station / Department of Analytical Chemistry; A.D. Servin, The Connecticut Agricultural Experiment Station / Analytical Chemistry; R. De La Torre Roche, Connecticut Agricultural Experiment Station / Department of Analytical Chemistry; S. Majumdar, A. Mukherjee, The Connecticut Agricultural Experiment Station / Analytical Chemistry; L. Pagano, University of Parma / Life Sciences

The trophic transfer of engineered nanoparticles from soil through terrestrial food chains is being evaluated. Cerium oxide and lanthanum oxide bulk and nanoparticles (NP) were added to soil (0-1000 mg/kg) with zucchini or lettuce plants, respectively. Additionally, studies have been initiated in which lettuce was added to soil 0 or 70 d after amendment with copper oxide NP, bulk and ions (0-400 mg/kg). The plant Ce, La and Cu accumulation was determined by ICP-MS and leaves were fed to crickets or darkling beetles for 14 days. Crickets were then fed to secondary consumers; wolf spiders, mantids or lizards for 7 or 14 days. The Ce, La and Cu accumulation in the primary/secondary consumers and cricket/lizard feces were also measured. Results from the Ce experiment showed that zucchini Ce content was significantly greater with the NP exposure. The flowers, leaves, stems, and roots of bulk exposed plants contained 93.3, 707, 331, and 119,000 ng/g, respectively; nanoceria-exposed plants contained 153, 1510, 479 and 567,000 ng/g, respectively. Crickets fed bulk and NP-exposed leaves contained 15 and 34 ng/g, respectively. Spiders consuming bulk-exposed crickets had non-detectable Ce but NP-fed spiders contained Ce at 4.9 ng/g. Upon lanthanum exposure, lettuce mass was reduced across all treatments but there was no difference in lettuce La content based on particle size. Although the CuO experiment is ongoing, preliminary results from pigment content/production showed no significant effects in lettuce from the two soils (0 or 70-d weathered Cu) upon Cu treatments exposure. Interestingly, expression levels of several target genes involved in Cu transport suggest that the mechanisms involved in CuO NPs accumulation are differentially regulated as compared to ionic Cu. Additional results focused on accumulation of Cu in plant, crickets and lizard tissues will also be presented.

Approaches towards predicitng the tecotoxicity of nanomaterials

W. Peijnenburg, RIVM / Center for Safety of Substances and Products; M.G. Vijver, G. Chen, CML Leiden University

Nowadays, nanomaterials are highly integrated into our daily life. However, recent studies have shown obvious toxicity of some nanoparticles to living organisms, and their potentially negative influence on environmental ecosystems. The goal of the present study was to develop predictive models that allow to efficiently predict the ecotoxicological properties and effects of inorganic nanomaterials (metals and oxides). The numerical data on toxicity of nanoparticles to different organisms have been taken from the literature and were uploaded in a data base. The main characteristics of nanoparticles such as chemical composition of nanoparticles, average particle size (APS), shape and information about the biological test species were used as obligatory condition for all properties in the data base. 20 QSAR-type of models were compared by following the same procedure with different combinations of descriptors and machine learning methods. The QSAR methodologies applied, used Random Forests (WEKA-RF), k-Nearest Neighbors and Associative Neural Networks. The predictive ability of the models was tested through leave-one-out cross-validation, giving a $q^2=0.69$-0.78 *for regression models and total accuracies Ac=73-99% for classification models. Predictions for external evaluation sets obtained accuracies in the range of 69-85% (for low/high toxicity classifications) and* $q^2=0.70$-0.78 *for regressions.The method showed itself to be a potential tool for estimation of toxicity of new nanoparticles at early stages of nanomaterial development.*

QSAR Models for heterogeneous Nanoparticles: Results from the COST Action TD1204 MODENA - WG3 Exercise

E. Papa, Department of Theoretical and Applied Sciences

This study shows partial results generated by the author within the context of the COST Action TD1204 'Modelling Nanomaterial Toxicity' (MODENA). This action was launched in 2012, and generated a network of scientists currently active to promote trans-disciplinary cooperation on the topic of computational nanotoxicology. A main output of this cooperation has been the creation of a large dataset with cytotoxicty data measured in different cell lines for heterogeneous nanoparticles (NPs) by 9 laboratories operating within MODENA. This dataset was shared among members of the Working Group 3 (WG3 - modelling) in order to investigate the possibility to generate models on such dataset. This dataset included 192 heterogeneous NPs representative for 11 different metals and materials (i.e. Ag, Au, Fe, Co, Ni, Si, Ce, C, Ti, Zn, PLGA-PEO), structurally characterized by experimentally measured properties, such as shape, size, surface area etc.. Approaches based on Quantitative Structure Activity Relationships were applied to predict different responses of biological activity represented by EC_{25} and EC_{50} values measured in human cell cultures, using four cytotoxicity assays (i.e. ATP assay, LDH assay, MTT assay, and WST-1 assay). The models were developed by using the software QSARINS by Multiple Linear Regression (MLR - Ordinary Least Squares (OLS) method), performing exhaustive search i.e. by exploring all the possible combinations of variables. The best models were chosen as those with the best statistical performances according to various validation parameters. This study confirmed the scientific relevance of the dataset created within MODENA starting from data generated independently by different laboratories, and without a priori supervision. The coherency of the information included in the data set was captured by the modelling approach which identified robust structure-activity relationships on the basis of interpretable descriptors. A main issue emerged regarding the dependency of the quality of the models on the metric used to express toxicity. Results show that the metric "number of NPs/ml" gives the best modelling performances, and thus may be suggested as preferable metric to generate QSAR models for heterogeneous datasets.

Polar ecotoxicology: hot issues in cold climates!

Influence of environmental and ecological factors on plasma perfluoroalkyl substances (PFASs) in female polar bears (Ursus maritimus) from the Barents Sea

S. Bourgeon, Department of Arctic Marine Biology; J. Aars, The Norwegian Polar Institute; A. Polder, Norwegian University of Life Sciences / Department of Food Safety and Infection Biology; H. Routti,

Perfluoroalkylated substances (PFASs) are synthetic chemicals used for various industrial purposes since the 1950s. The most commonly detected groups of PFASs in biota are perfluoroalkylated sulfonic acids (PFSAs) and perfluorocarboxylic acids (PFCAs). Many PFASs are highly persistent and have similar biomagnification capacity as lipophilic persistent organic pollutants (POPs), such as polychlorinated biphenyls (PCBs) and chlorinated pesticides in Arctic marine food webs. In contrast to PCBs and chlorinated pesticides, PFASs have strong affinity to protein-rich tissues such as liver and blood. The concentrations of these emerging compounds in Arctic marine predators such as polar bears (*Ursus maritimus*) are comparable or higher than PCBs and chlorinated pesticides. The high concentrations of PFASs in Arctic apex predators are of great concern due to their potential health effects such as metabolic disruption, developmental toxicity, thyroid disruption, immunological effects and neurotoxicity. Throughout their life cycle, polar bears alternatively accumulate and lose massive fat depots following the fluctuations in accessibility of their prey. In this context, the current study aimed at examining the environmental (i.e., season, year and diet) and ecological factors (i.e., breeding status and space use strategy) on plasma PFASs in female polar bears from the Barents Sea. To do so, we sampled females with variable reproductive status (i.e., solitary, with cubs of the year or with yearlings) over two seasons (spring and autumn) and two years (2012 and 2013). The concentrations of only three compounds were influenced by the season (PFNA, PFDA, PFTriA) and one compound by the breeding status of females (PFTriA). All PFASs compounds were explained by a dietary tracer ($\delta^{15}N$ RBC) implying an influence of diet on PFASs exposure. Moreover, $\delta^{15}N$ RBC and most compounds were significantly influenced by the space use strategy of females with pelagic females showing higher $\delta^{15}N$ RBC and higher plasma concentrations of PFASs compared to local females. Our results suggest that the influence of dietary exposure on plasma concentrations of PFASs is driven by the space use strategy of females. This further suggests a possible indirect role of climate change in PFASs exposure through alterations in migration patterns of polar bears (i.e., the ecology of species).

539
How do pollutants and fat get along? Insights in a "feast and fast" specialist, the polar bear.
S. Tartu, Norwegian Polar Institute / Ecotoxicology; S. Bourgeon, University of Tromsø; J. Aars, The Norwegian Polar Institute; A. Polder, Norwegian University of Life Sciences / Department of Food Safety and Infection Biology; A. Goksøyr, University of Bergen / Department of Biology; R. Lille-Langøy, University of Bergen; T. Størseth, SINTEF / Environmental Technology; H. Routti, The Norwegian Polar Institute
Changing climate will challenge arctic animals energetically. For example, prolongation of ice-free summer seasons will lead to prolonged fasting periods of polar bears, which use sea ice as a platform for hunting. Fasting is physiologically demanding and requires optimal control of energy homeostasis. Energy deficiency places greatest demands for reproducing females and may ultimately affect reproductive success and population recruitment. Peroxisome proliferator-activated receptors (PPARs) play a central role in regulating energy homeostasis. Recent research indicates that several currently used chemicals, may disturb the function of PPARs. We hypothesize that contaminant exposure may affect the energy homeostasis of polar bears and thus decrease their ability to respond to climate change. To explore our hypothesis, we measured PPARγ mRNA expression in adipose tissue and related it to legacy chlorinated and brominated pollutants. PPARγ mRNA expression was positively related to most pollutants. We also analyzed metabolomics, which is a comprehensive study of low molecular weight water-soluble metabolites. This methodology can give mechanistic insight into changes in metabolism due to a stressor such as fasting. We tested the relationships between metabolome and fasting, as depicted by the urea/creatinine ratio in plasma. We observed a negative relationship between metabolome (characterized by lipid fingerprints) PCA scores and urea/creatinine. Additionally, we observed a positive relationship between lipid fingerprints PCA scores and ΣChlordanes in autumn but not spring. Consequently, our results suggest that several pollutants can disrupt lipid storage and possibly lipid stores' functionality, this could impair the ability of polar bears to adapt to climate changes.

Lipophilic Persistent Organic Pollutants as Indicators of Adiposity in Humpback Whales
S.M. Bengtson Nash, Griffith University / Southern Ocean Persistent Organic Pollutants Program; P. Eisenmann, J. Castrillon Posada, Griffith University / Southern Ocean Persistent Organic Pollutants Program SOPOPP
Southern hemisphere humpback whales are naturally obese mammals, highly adapted to the productivity extremes of Polar latitudes. Multiple research disciplines are alerting us to progressive weight loss and changing foraging habits in these populations, signalling underlying ecological change. Despite the potential gravity of this trend, unravelling the nutritional signals of humpback whales to provide an unambiguous evaluation of species energy reserves, and therefore vulnerability to ecological change, is hindered by the inadequate power of existing non-lethal, cetacean research approaches. Humpback whale external blubber adipocyte area analysis has recently found, by the investigative team, to be adequately powerful to distinguish between “fed” and “fasted” migrating cohorts. Similarly, the investigative team has previously shown the dramatic concentration effect that occurs in outer blubber Persistent Organic Pollutant (POP) levels between the two migrating cohorts, lending support for both paramters as indirect measures of energetic reserves. Here we demonstrate inter-annual fluctuations in energetic reserves as revealed by these parameters in combination with stable isotope analysis. We advocate the scrutiny of POP burdens in long term monitoring programs, as indirect indicators of energetic health.

541
From Antarctica to the subtropics: latitudinal differences in trace element and organic pollutant contamination in Southern Ocean skuas (Catharacta spp.)
a. carravieri; P. Bustamante, LIENSs CNRS & Université de la Rochelle UMR 7266 / LIENSs; P. Labadie, University of Bordeaux / UMR EPOC Equipe LPTC; H. Budzinski, University of Bordeaux / UMR EPOC LPTC; O. Chastel, Y. Cherel, CEBC CNRS Université de la Rochelle UMR
Polar seabirds integrate bioaccumulative contaminants via food intake and have revealed geographical and temporal trends of contamination, especially in the Arctic. By contrast, spatio-temporal patterns of contamination of Antarctic and subantarctic food webs are still poorly known. Pre-fledging seabird chicks are particularly interesting as bioindicators of food web chemical contamination, because their food and their parents’ foraging ecology during the chick-rearing period are relatively well-known. Hence, concentrations in chick tissues are more easily related to dietary sources and represent primarily the local environment. Here we measured mercury (Hg) and 13 other trace elements, and persistent organic pollutants (POPs, including organochlorine pesticides and polychlorinated biphenyls) in blood of skua chicks from four breeding locations that encompass a large latitudinal range in the southern Indian Ocean: from Antarctica (Terre Adélie, Catharacta maccormicki), through subantarctic areas (Crozet and Kerguelen Islands, C. lonnbergi), to the subtropics (Amsterdam Island, C. lonnbergi). Concentrations of the highly-toxic Hg increased from chicks in Antarctica to chicks in the subantarctic and subtropical islands, with a factor of eight between the populations with the lowest and highest burdens (0.5 ± 0.1 vs. 4.0 ± 0.8 $\mu g\ g^{-1}$ dry weight, mean ± SD, at Terre Adélie and Amsterdam Island, respectively). Selenium (Se) concentrations were extremely high in some skua populations, reaching levels never shown before in any bird species. Se was positively associated to Hg, suggesting its involvement in protective mechanisms against Hg toxicity. Chicks’ POP pattern was largely dominated by pesticides, in particular DDT derivatives and hexachlorobenzene (HCB). Overall, POP concentrations were low, although HCB levels were comparable to related species from the Northern Hemisphere. Skua chicks from the subtropical site had lower levels and diversity of POPs than those of the subantarctic and Antarctic populations. The strong inter-site differences in Hg and POP levels highlighted in the present study are consistent with previous results showing a latitudinal trend in the incorporation of these contaminants in Southern Ocean food webs. The skua populations studied here could serve as useful models to investigate the potential effects of these contaminants on seabird physiology and demography.

542
Contaminant loads in relation to wintering area and breeding habitat in the Arctic Skua
S. Hanssen, Norwegian Institute for Nature Research; E. Skottene, Norwegian University of Science and Technology; D. Herzke, Norwegian Institute for Air Research NILU; B. Moe, Norwegian Institute for Nature Research NINA
Seabirds are often used as model species in ecotoxicological studies as they are near the apex of most marine food chains, and therefore bioaccumulate high concentrations of certain pollutants. Most seabirds that breed in temperate and Arctic regions are migratory, and therefore spend a considerable part of the year away from their breeding areas thereby functioning as biovectors. Several studies have implied that migration may have considerable effects on seabird ecotoxicology. In this study, we have studied migration strategies in the arctic skua *Stercorarius parasiticus*. It breeds in arctic and subarctic areas, and in Svalbard and Northern Norway, it spends the nonbreeding part of the year (September through May) away from the breeding grounds. We have used Global Location Sensor (GLS) loggers to track the migration strategies of the same individuals over several years. This has revealed different individual wintering areas spanning large parts of the Atlantic Ocean. We report that the individual birds repeatedly target the same winter area year after year. We have analyzed various pollutants such as heavy metals and PCBs to look for individual differences in contaminant load related to different wintering areas and breeding habitat in the Arctic.

543
Do reproductive strategies affect pollutant levels in pinnipeds? A meta-analysis
D.J. Hitchcock, University of Oslo; . Varpe, University Centre in Svalbard; T. Andersen, University of Oslo / Department of Biosciences; K. Borga, Department of Bioscences, University of Oslo / Department of Biosciences
In highly seasonal environments where food availability can be limited, such as the Arctic, animals depend on the use of stored energy reserves. Species store energy as lipids which they can allocate towards survival, growth and reproduction. Animals that store energy prior to reproduction are described as â_capital breeders’, and those that feed during reproduction as ‘income breeders’. In marine mammals such as seals, breeding substrates (fast ice and land vs. drift ice) and access to food resources during the breeding period can determine which

strategy a species may adopt. In polar habitats such as the marginal ice zone where ice is unstable and food is temporally limited, capital breeding is favoured. However, the use of lipids means that persistent organic pollutants (POPs) are also stored, remobilised and maternally transferred during reproduction, especially during lactation. Most studies on maternal pollutant transfer have investigated only single species, meaning that a study synthesising the overall effect of life history strategy on the bioaccumulation pollutants is lacking. A meta-analysis was conducted to test the effects of reproductive strategy (income and capital breeding) on pollutant levels in mother-pup seal pairs. Reproductive strategy was measured as pup daily mass gain during lactation, with capital breeding pups gaining more weight per day than income breeding pups. The meta-analysis showed that capital breeding mothers transferred more lipid soluble POPs such as polychlorinated biphenyls (PCBs) to their pups than income breeders. On the other hand, protein associated pollutants such as mercury (Hg) was not transferred as efficiently by either reproductive strategy, compared to lipid soluble POPs. Studies with data on unrelated juveniles and adult females in the same population were also compared and pup daily mass gain was found to be a poor descriptor of pollutant levels across seals, most likely because using direct mother-pup seal pairs are best suited to studying the effects of reproductive strategies. In summary, offspring of capital breeders are at greater risk to negative health effects as they are exposed to higher levels of pollutants than income breeders, given similar POP levels across female seal species. These findings are of particular importance in polar regions, where species have adapted to utilise stored energy reserves, and are especially relevant when considering how these areas are affected by climate change.

Soil and water contaminants: evaluation, biomonitoring and bioindicators for effective management (II)

Nutrients in urban surface waters: urban aquatic ecosystem threat and water re-use

O.S. Olatunji, Cape Peninsula University of Technology / Chemistry; B. Opeolu, Cape Peninsula University of Technology / Faculty of Applied Sciences; O. Fatoki, B.J. Ximba, Cape Peninsula University of Technology / Chemistry

Introduction Domestic and industrial discharges into urban surface waters including streams and rivers can result in nutrient enrichment, de-oxygenation and reduction of freshwater quality. This could lead to increased hazard in waste water re-use, and threat to urban aquatic ecosystem diversity and human health. This study investigates the levels of dissolved oxygen (DO), oxygen demand (BOD, COD), inorganic nutrients ($N\text{-}NO_3^-$, $N\text{-}NO_2^-$, $N\text{-}NH_4^+$ and $P\text{-}PO_4^{3-}$) and organic carbon (OC) in Ogunpa River (an urban surface waters) in Ibadan metropolis, Oyo State, Nigeria. **Materials and methods** Water samples were pooled at the Ogunpa River source and at different sampling stations in different area location along the Ogunpa River. The water samples were prepared and analysed using standard methods. **Results and discussion** pH Organic carbon % DO mg/L BOD mg/L COD mg/L $N\text{-}NO_3^-$ mg/L $N\text{-}NO_2^-$ mg/L $N\text{-}NH_4^+$ mg/L $P\text{-}PO_4^{3-}$ mg/L Minimum 6.8 2.1 2.85 7.39 2.11 7.34 6.19 0.085 2.83 Maximum 7.4 3.6% 5.37 10.52 8.67 9.58 7.85 0.51 9.68 The DO, BOD, COD ranged, 2.85 – 5.37 mg/L, 7.39 – 10.52 mg/L, 2.11 - 8.67 mg/L respectively. Organic carbon and pH ranged 2.1 – 3.6% and 6.8 – 7.4 respectively, while $N\text{-}NO_3^-$, $N\text{-}NO_2^-$, $N\text{-}NH_4^+$ and $P\text{-}PO_4^{3-}$ were, 7.34 – 9.58 mg/L, 6.19 - 7.85 mg/L, 0.085 – 0.51 mg/L, and 2.83 - 9.68 mg/L respectively. The high nutrient concentrations of the water, may be attributed to unsustainable release of high nutrient streams and disposed solid wastes. This results in the undesirable effects of corrosion and incrustation observed in most sampling stations, leading to the drop in DO and thus the high COD and BOD. **Conclusion** In effect, the self-purification and regeneration capacity of the water is low due to consistent exposure. This suggests high cost of water treatment for re-use. An appropriate monitoring and management procedure is therefore required to improve the water quality, and sustain the ecosystem.

New tool of multi component three-phase exposure: Bioavailability and mobility of organic contaminants in solid phase samples

A. Necasova, Masaryk University, Faculty of Science, RECETOX / Research centre for toxic compounds in the environment RECETOX; Z. Prokop, Masaryk University / Research centre for toxic compounds in the environment RECETOX; J. Klanova, P. Cupr, Masaryk University / RECETOX Research centre for toxic compounds in the environment

The bioavailability plays crucial role in ecological risk assessment of soil contaminants. There are two approaches of environmental risk assessment, the biological and chemical, which complement each other. We developed a novel approach for rapid assessment of bioavailability and potential mobility of soil contaminants. The response of the same test organism to the organic extract, water extract and solid phase of soil was recorded and compared. This approach was designed to give an initial estimate of the total organic toxicity (response to organic extractable fraction), as well as the mobile (response to water extract) and bioavailable fraction (response to solid phase) of soil samples. The selected soil samples with different level of contamination (PAHs, PCBs, HCH and DDT) and different amount of organic carbon was used to demonstrate the efficiency of proposed method for analysis of contaminants fractionation in solid samples. The results showed a low potential mobility of organic toxicants in tested soils. The bioavailable fraction was significantly greater than the mobile fraction. Still, the large fraction of overall contamination was strongly bound to the solid samples showing significant dependence on the amount of organic carbon. The fraction bioavailable to the test microorganism was likely elevated by the effect of driven desorption. The presented new tool of "multi component three-phase exposure" utilise the exposure of the same test organism and it is useful for evaluation of total toxicity, water soluble and biologically available fraction of the solid sample contamination. The three-step ecotoxicological evaluation provides early information about behaviour of contaminants in soils in the context of mobility and bioavailability. The knowledge of mobility and bioavailability of chemical compound in a soil is useful for the hazard identification (provides useful toxicity and exposure information) and environmental risk assessment for organic contaminants in soils.

546

Novel β-FeOOH/NiO composite material as potential catalyst for ozonation of organics

O. Fatoki, Cape Peninsula University of Technology / Chemistry; O. Oputu, Cape Peninsula University of Technology / Analytic Chemistry

This study reports the on novel synthesis of an organic linker mediated nano composite comprising of β-FeOOH and NiO and its possible application to heterogeneous ozone catalysis. The synthesized composite material was characterized using XRD, FTIR, TEM. Elemental mapping of single composite material under dark field scanning mode confirmed the presence of both Ni and Fe in the composite. 4-chlorophenol (4-CP) was used as target molecule to evaluate the catalytic activity. Above 5 % β-FeOOH loading on NiO, catalytic efficiency reduced. The composite material was stable under acidic (pH 2.5) and alkaline (pH 10), with the resulting solutions having no traces of Ni or Fe as evident from AAS measurements. Catalytic ozonation removed 85 % of 4CP in 20 minutes compared to 47 % removed by ozonation alone. The catalyst showed good recyclability as the catalytic activity of the material could be restored after calcination. The catalytic activity of the composite was due to the higher generation of $OH^?$ as shown by photoluminescence experiments. This novel composite material therefore shows as a future catalyst in water purification processes.

547

The sorption of active pharmaceutical ingredients onto soils under different pH and microbial conditions

K. Lees, Plymouth University / Biogeochemistry Research Group; M. Fitzsimons, Plymouth University; J. Snape, AstraZeneca UK Ltd. / AstraZeneca Global Environment; A. Tappin, Plymouth University; S. Comber, Plymouth University / Environmental Science

Population growth, increasing affluence, and greater access to medicines have led to an increase in active pharmaceutical ingredients (APIs) entering sewage networks. In the low and lower-middle income countries (LLMIC) of Asia, Africa and Central and South America, the use of human pharmaceuticals increased by 23-29 % between 2000 and 2011. As a consequence, the loadings of residual APIs and other down the drain chemicals (including personal care products (PCPs) and cleaning agents to soils, surface and ground waters of these countries are increasing. In areas with high wastewater reuse residual quantities of APIs may enter agricultural soils via irrigation with treated, partially treated, or even untreated wastewater and sludge. Wastewater used for irrigation is currently not included in chemical environmental risk assessments (ERAs) and requires further consideration in areas with high water reuse. The aims of this research were to measure the influence pH and the soil microbial community has on the sorption of three APIs to soil. Propranolol, naproxen and ofloxacin were chosen as the APIs to focus on in these experiments as they cover a wide range of API characteristics and are widely used throughout LLMICs. The OECD 106 technical guideline was used to generate data on the adsorption and desorption kinetics for the three APIs using two soil types under natural, pH altered and sterilised soils. Future work as part of this project will include applying minimally treated wastewater to the soils and measuring how API sorption and degradation is affected and column experiments to assess leaching potential to groundwater sources. The data gathered through these experiments will aid the development of robust ERAs for APIs in soil for wastewater irrigation.

548

Fate of metamitron in soil - a detailed insight into its biotransformation pathways and biogenic residues formation

K. Nowak, RWTH Aachen University / Institute for Environmental Research Biology V; S. Wang, Helmholtz Centre for Environmental Research UFZ / Dept of Environmental Biotechnology; A. Schaeffer, RWTH Aachen University / Institute for Environmental Research; A. Miltner, M. Kästner, Helmholtz centre for environmental research - UFZ / Department of Environmental Biotechnology

Metamitron (MTR) is commonly used in sugar beet crops and has received great concern due to its wide application. Although many studies addressing MTR behaviour in the soil systems are available, the detailed insight into its microbial turnover is still missing. We investigated biotransformation of MTR with the particular focus on the metabolic incorporation of the isotope label into FA and AA and their fate in soil over time. In biotic system, the mineralization of MTR started immediately without any lag reaching finally 60% of the initial $^{13}C_6$-metamitron equivalents. In contrast to biotic system, abiotic system showed a lower mineralization, amounting 7.4% of the initially added $^{13}C_6$-metamitron MTR was degraded initially to desamino-metamitron in soil and water-sediment might be assigned to microbial growth. Desamino-metamitron is ultimately converted to pyruvate and acetaldehyde. Pyruvate is used for direct synthesis of alanine as proven by the dominant presence of ^{13}C-alanine throughout the experiment, including both growth and starvation conditions. In addition, pyruvate and acetaldehyde entering the tricaboxylic acid cycle contributed indirectly to glutamate synthesis via 2-oxoglutarate and may explain high contents of ^{13}C-labelled glutamate. The complete dissipation of desamino-metamitron from soil after 16 days together with a rapid mineralisation of MTR leaving only traces of MTR in soil on day 16 suggests the relevance of this pathway in active metabolism. Based on the measured content of total AA (14.85% of $^{13}C_6$-metamitron equivalents) we could estimate that 29.7% of carbon-derived MTR was assimilated by microorganisms. At the end, ^{13}C-label derived from MTR was distributed mainly between $^{13}CO_2$ and microbial biomass indicating a complete degradation of this herbicide in soil. Using stable isotope label tracer (^{13}C), we established a detailed MTR turnover mass balance and metabolic fate analysis including biogenic residues formation. The presented data showed that nearly all NER were biogenic and were based on non-toxic biomass compounds stabilized in the SOM. In addition, we proved for the first time that MTR was utilized as a C source and was biodegraded via two pathways the "desamino-metamitron" and via the "Rhodococcus pathway".

549
Threatened southern African soils: Status and challenges from an (eco)toxicological risk assessment perspective
H. Eijsackers, North-West University; A. Reinecke, Stellenbosch University / Botany and Zoology; S. Reinecke, Stellenbosch University / Dept Botany and Zoology; M. Maboeta, North West University / Unit for Environmental Sciences and Management
Soils in Southern Africa (SA); comprising South Africa, Namibia, Botswana, Zambia and Zimbabwe are, in terms of area, not a limited resource but are in terms of arability. This is due to limited rainfall in the area and inherent poor physical condition of these soils. As in the rest of the world soils in SA are threatened by a range of anthropological activities e.g. mining, agriculture and industry. Ecotoxicological risk assessment (RA) of soils has been well studied worldwide. Although some risk assessment of soils has been done in SA it has not been extensive. Soil screening values exist in South Africa, which enables soil quality assessment, but lack a clear risk-based scientific foundation and site-specific risk assessment. This is especially important because of the vast mining activities and the proximity of mine tailings disposal facilities to residential areas; exposing people living close by to a wide range of possible contaminants. We ask the question; to what extent the developed general RA systems used in other parts of the world are valid for the specific conditions in SA? We also investigated the status of the (eco)toxicological research in SA. This presentation intends to give an analysis and overview of the present situation, highlight the impacts on soil in SA, and assess current research as well as identifying knowledge needs and gaps.

Multiple stresses in aquatic ecosystems: Assessment of stress response and its consequences in organisms (II)

Cross effects of salinity and ceria nanoparticles on two endobenthic bivalves Corbicula fluminea and Scrobicularia plana: multibiomarker assessment
C. Bertrand, Université de Lorraine, CNRS UMR 7360; S. Devin, LIEC - Université de Lorraine - CNRS / LIEC CNRS UMR; C. Mouneyrac, MMS UCO; M. Auffan, CEREGE / International Consortium for the Environmental Implications of Nanotechnology; A. Chatel, Université Catholique de lOuest / Sciences Environnement; V. Koehle-Divo, Université de Lorraine CNRS UMR; C. Pagnout, LIEC - Université de Lorraine - CNRS / LIEC CNRS UMR; S. Pain-Devin, Université de Lorraine - UL / LIEC CNRS UMR; A. Pariat, AixMarseille Université CNRS CEREGE; H. Perrein, Université Catholique de lOuest / MMS; L. Poirier, A. Zalouk-Vergnoux, Univeristé de Nantes / MMS; L. Giamberini, Université de Lorraine, CNRS UMR 7360 / LIEC CNRS UMR
Cerium nanomaterials (CeNMs) are integrated in numerous consumer products (e.g. wood stain, painting, fuel additive) because of their strong abrasive power, high resistance and UV-shielding properties. Given the production volumes of CeNMs and their potential release into the aquatic environment, assessment of the potential environmental risks of CeNMs is a priority. While the impacts of Engineered Nanomaterials (ENMs) in freshwater media have been largely studied this last decade, data covering a salinity gradient are scarce. The aim of the present study is to assess the fate, behaviour and toxicity effects of both CeNMs included in a commercial fuel additive (Envirox™) at two stages of its life cycle and of NM-212, a standardized CeNMs provided from Joint Research Centre, across a salinity gradient (1.5, 15.0 and 30.0 practical salinity unit) during 28 days. Two euryhaline bivalves were selected: Corbicula fluminea and Scrobicularia plana, representative of freshwater and estuarine environments, respectively. Both species are well recognized as good models for biomonitoring purposes. These filter-feeding species may be particularly at risk of ENM exposure since they live at the water-sediment interface. C. fluminea were exposed to a constant water volume at 1.5 and 15 psu; while S. plana were exposed to an artificial rhythm of tide at the laboratory (6 h high tide/ 6 h low tide) at 15 and 30 psu. The contaminants were added gradually every 3 days (90 μg Ce /L) during the whole duration of experiment. The size, shape and cristallography of the uncombusted and combusted Envirox™ were performed by Transmission Electron Microscopy (TEM). Total Ce in the water column, labile forms of Ce accumulated in Diffusive Gradient Thin film (DGT) tools and Ce concentrations in the digestive glands of bivalves were estimated by ICP-MS. After 7, 14, 21 and 28 days of exposure, individuals were submitted to burrowing tests. Toxicity responses of both bivalve species were evaluated using a multi-marker approach at different levels (sub-cellular, individual) of biological organization using an adjustable pocked-size marine and freshwater mesocosm platform. Results showed in both species a significant difference of biomarker responses according to salinity, exposure condition and exposure time. Moreover, the differences between the conditions of exposure were discriminated with a reduced set of biomarkers: cellular damage, antioxidant defences, cellular respiration condition.

551
Environmental health assessment of the Seine estuary using a battery of indicators at different levels of biological organization
A. Barrick, Université Catholique de lOuest / LUNAM Université Mer Molécules Santé MMS; H. PERREIN-ETTAJANI, University Catholique de lOuest / Biologie Environnement; A. Chatel, Université Catholique de lOuest / Sciences Environnement; M. Mouloud, P. Gillet, M. Bruneau, Université Catholique de lOuest / LUNAM Université Mer Molécules Santé MMS; C. Mouneyrac, Université Catholique de lOuest / UNAM Université Nantes Angers Le Mans Mer Molécules Santé MMS
It is estimated that the global economic scale of environmental damage due to anthropogenic activities in coastal zones and estuaries is approximately $12.6 trillion per year. The Seine estuary is of particular concern as it is influenced by twenty-five percent of France's population and forty percent of the countries' industrial and agricultural runoff. The aim of this study, which is a part of the ECOTONES project, led by the GIP Seine-Aval, is to utilize a multi-disciplinary approach to assess the health status of a key invertebrate of estuary functioning: the annelid polychaete *Hediste diversicolor*. The approach is based on endpoints at multiple levels of biological organization (cellular, individual, population) so as to estimate the overall health of this species in the Seine estuary. For each biomarker studied (acetylcholinesterase: AChE, catalase: CAT, glutathione *S*-transferase: GST, superoxide dismutase: SOD, thiobarbituric acid reactive substances: TBARS, energy reserves), results of the current campaign (March 2015) in Seine were compared to historical data previously acquired from samples collected in reference sites (Authie and Bourgneuf). *H. diversicolor's* population trends depicted lower biomass and density, smaller individuals with delayed reproductive potential compared to samples from reference sites. Biochemical biomarkers results also indicate that ragworm was being severely impacted at the cellular level exhibiting low levels of energy reserves (glycogen and lipids), of AChE activity (neurotoxicity), and of GST values suggesting defense mechanisms being overwhelmed. The high levels of Catalase and TBARS compared to values of reference sites suggest an oxidative stress endured by organisms. In addition, a predictive model for BAC and EAC determination using a linearized regression model (with "K-means clustering" method) has been developed. **Keywords**: Levels of biological organization, *Hediste diversicolor,* Biomarkers, Background and Environmental Assessment Criteria.

552
Adaptive responses of a marine filter-feeder, the common blue mussel, to chronic contamination in a harbour located within urbanized environment.
M. AUFFRET, IUEM / LEMAR UMR; A. MESNIL, C. LACROIX, Universite de Bretagne Occidentale / IUEM; M. CACHERA, Université de Bretage Occidentale / IUEM; I. BOUTET, Université de Bretagne Ocidentale / IUEM; C. SEGUINEAU, Universite de Bretagne Occidentale / IUEM
Conjugated effects of chronic contamination and temperature increase affecting coastal waters are to be addressed by marine biologists when considering global change in the ocean. Adaptive responses of a marine filter-feeder, the common blue mussel *Mytilus spp*., have been investigated in a pseudo-estuarine area, the Bay of Brest (Brittany, France). Shipping activities in the medium-sized harbor of Brest with both trade and navy port have generated for decades a chronic contamination by POPs. Actual contamination levels have been established in mussel tissues. To assess biological responses to environmental pressure, the activity of several enzymes involved in major physiological functions, including metabolism and biotransformation/detoxication, has been measured along with biometric and overall health parameters. In order to consider the intra-population

variability, several cohorts were recognized based on shell length and further sampled. Considering that two species, *M. edulis* and *M. galloprovincialis*, and their hybrids are sympatric in this geographical area, the genetic status of each individual has been determined by using molecular methods. As a complement to these observations in native individuals, mussels collected at a distant and less contaminated site in the Bay have been caged in the harbor. After one month, contrasted, biochemical responses among groups suggested an adaptive process in native mussel in order to overcome deleterious effects of environmental stress. This set of observations could contribute to a better understanding of how biological responses are induced in the blue mussel which is becoming a major sentinel species in the survey of global changes effects in coastal ecosystems.
Keywords: Coastal ecosystems, anthropogenic pressure, invertebrates, adaptation
This work was supported by a grant from both ANR and NSERC Agencies (joined project France-Canada) as a part of the research project IPOC (Interactions between POllution and Climate changes: Development of improved monitoring strategy, ANR-12-ISV7-0004-01, 2013-2015)

553
Multiple stressors influencing seagrass dynamics in a shallow Mediterranean lagoon
N. Diepens, Wageningen University; Y. Cherain, E. Coulet, National nature reserve of Camargue; A. Probst, E. Buffan-Dubau, ECOLAB UMR CNRS UPS INPT; J. Kallerhoff, ECOLAB UMR CNRS UPS INPT / Ecolab Laboratoire décologie fonctionnelle et environnement; G. Merlina, ECOLAB UMR CNRS UPS INPT; J. Silvestre, ECOLAB UMR CNRS UPS INPT / ECOLAB UMR CNRS UPS INPT; O. Boutron, P. Grillas, Tour du Valat, Research centre for the conservation of Mediterranean wetlands; A. Elger, University of Toulouse / EcoLab
Seagrasses have a wide spatial distribution, form an important component of many coastal ecosystem and provide essential ecosystem services. Seagrass declines have been observed worldwide due to a variety of (multiple) stressors. The shallow Vaccarès lagoon, Camargue, France is an example of a highly important coastal lagoon situated in a Mediterranean river delta and is surrounded by intensive agriculture. *Zostera noltei* is the dominant macrophyte species and suffered two major declines in 1997 and 2008. The first decline was well explained by salinity and turbidity, whereas the second decline could not be explained by these parameters. Other stressors such as chemicals, nutrients or temperature could be explanatory variables for the second declines. The main aim was to understand the influence of multiple stressors on seagrass physiology and population dynamics in a typical Mediterranean shallow lagoon (Vaccarès lagoon) by analysing the biological, environmental and chemical data. Contamination by pesticides and metals was monitored in water and sediments both in the lagoon and in its main tributaries from 2011 to 2014. The recent dynamics of seagrass was quantified across the lagoon using a 55-points sampling design. Three stress biomarkers were measured *in situ*: photosynthetic pigment composition, chlorophyll fluorescence and rhizome sugar content. Biological, environmental and chemical parameters were analysed by co-inertia analysis. GIS was used to interpolate between measured data points. Co-inertia analysis showed a significant relationship between environmental data and seagrass status matrices. Seagrass dynamics were negatively correlated to the concentrations of some herbicides in water (2,4-MCPA and bentazone) and with metals in sediments (arsenic). Rhizome starch content in winter was negatively correlated to those herbicides and to several metals (arsenic, zinc, copper) in water and/or sediments. These results suggest that environmental contamination may be responsible for the decline of seagrass in some parts of the Vaccarès Lagoon. However, complementary investigations, such as longer monitoring and additional toxicity tests, are required to address the causal link between contamination and seagrass decline. Understanding the influence of multiple stressors on seagrass dynamics and thus possible declines is crucial for environmental risk assessment and to preserve these valuable systems with integrated management strategies.

554
Influence of environment on the response capacity to thermal stress in the blue mussel using experimental approach
I. BOUTET, Université de Bretagne Ocidentale / IUEM; C. LACROIX, Universite de Bretagne Occidentale / IUEM; A. Tanguy, UPMC; D. Moraga, Université de Breatgne Occidentale; M. Auffret, Universite de Bretagne Occidentale / LEMAR
In the intertidal zone, organisms are permanently exposed to strong environmental gradients and long periods of stressful conditions including hypoxia, temperatures and eutrophication. Temperature variations impact organisms at both biochemical and physiological processes directly, by restricting enzyme activity efficiency or promoting protein catabolism. Mussels of the genus *Mytilus* are one of the most important marine bivalves along the French coast at both economic and ecologic point of view. They colonized a wide range of environments from estuary to open coastal ecosystems and consequently challenged a large variety of fluctuating parameters such as salinity, temperature, tide, anthropic effluent. They are largely used as model species in biomonitoring programs and laboratory exposure studies. The present study aimed to investigate the cellular and transcriptomic response of mussels having been exposed to various levels of chronic chemical contamination (having distinctive environmental history) may respond to an experimental increase of temperature. In these experiments, blue mussels collected at two sites of the Bay of Brest were exposed in the laboratory to graduated warming and cellular and molecular responses relevant for physiological stress assessment were measured. In addition, considering that two mussel species (*M. galloprovincialis*, *M. edulis*) and their hybrids are present in the study area, we investigated possible differential responses in order to identify genetic basis of metabolic responses and further, differential sensivity of species to environmental, thermic stress. Results indicated various pattern of response when considering the different parameters analysed (population origin, temperature effect, tissue, hybrid status). Metabolic depression is observed at the highest temperatures for both populations studied but some differences remains at lowest temperature according to the site origin. More, hybrid mussels show some difference in their response compared to “pure” species *M. galloprovincialis* highliting the importance of hybridism in the species adaptation.

Identification and prioritisation of hazardous pollutants in the aquatic environment - the role of effect-directed analysis, monitoring and modelling (II)

555
Evaluation of exposure algorithms used for prioritisation of pharmaceuticals in the environment
E.E. Burns, University of York / Chemistry; J. Thomas-Oates, University of York / Chemistry Department; D.W. Kolpin, U.S. Geological Survey / Iowa Water Science Center; E.T. Furlong, U.S. Geological Survey / National Water Quality Laboratory; A. Boxall, University of York / Environment Department
Prioritisation methodologies provide potentially useful tools for identifying which from the plethora of current active pharmaceutical ingredients (APIs) could pose the greatest risk to the natural environment; thus focusing expensive laboratory testing or environmental monitoring towards APIs of greatest concern. The use of risk-based approaches that combine exposure and effect models with environmental measurements has become common practice. However, the reliability of these approaches is still unclear. Therefore, in this study we evaluated the accuracy of exposure algorithms commonly used for API prioritisation. An initial stream water occurrence study was conducted for 97 APIs in the City of York. These APIs covered a broad range of therapeutic classes and physico-chemical properties. Predicted environmental concentrations (PECs), obtained using prioritisation exposure algorithms, were then compared to measured environmental concentrations (MECs) to evaluate the general accuracy of predictions. Initial results reveal that the exposure algorithms for almost half of prescription APIs detected provided PECs that fell below MECs. Conversely, another third had a PEC/MEC ratio greater than 3, an overestimation indicating limited accuracy. A stepwise exclusion of select pharmaceutical fate considerations within the exposure algorithms included dilution, metabolism and wastewater treatment removal to target potential contributors to under- or overestimates of the PECs. Metabolism and wastewater treatment removal terms were identified as the largest source of deviation of PECs from MECs for the 97 APIs under investigation. Follow-up research will include a more detailed fate and transport study over a 12 month period to better understand the prioritisation algorithm components that are the driving factors behind the primary differences between PECs and MECs.

556
A Weight of Evidence Approach to the Eco-Risk Classification of Organic Chemicals Using Chemical Profiling of Hazard and Exposure
M.A. Bonnell, Environment and Climate Change Canada / Ecological Assessment Division; H. Swerdfeger, V. Dorais, Environment Canada; J. Arnot, ARC Arnot Research & Consulting Inc.
Environment Canada and Health Canada have begun the third phase of the Government of Canada’s Chemicals Management Plan (CMP3). Key to the planning of CMP3 was the development of efficient approaches to dealing with the large number of substances remaining to be addressed by 2020 as committed to be the Canadian Government under the SAICM agreement. A large number of organic substances have been addressed using Rapid Screening Techniques that largely focus on low tonnage thresholds (in silicotools and empirical data have been combined to generate substance profiles. A potency profile can include mode of toxic action, tissue reside toxicity ratios, receptor binding (estrogen/androgen), chemical activity, chemical reactivity (covalent interactions), aquatic and terrestrial foodweb hazard assessment factors (HAFs) generated using the Risk Assessment IDentification And Ranking (RAIDAR) model, bioactivity (TOXCAST/Tox21) and bioavailability. An exposure profile includes emission rate, overall persistence (P_{ov}), long-range transport, and the ratio of critical emission to actual emission as determined by the RAIDAR model for an emission to water. The potency and exposure profiles are compared to classification rules to determine the level of concern in the environment. Initial classifications are examined to determine robustness and consistency within a grouping afterwards resulting in final classifications. The approach will be demonstrated using 3 organic substances classified as higher, moderate and lower concern for CMP3.

557
Identifying the single most dangerous chemical present in UK surface waters following a risk ranking exercise
A. Johnson, CEH Wallingford / Wallingford; R. Donnachie, Centre for Ecology and Hydrology; M.D. Juergens, Centre for Ecology and Hydrology / Wallingford; C. Moeckel, Centre for Ecology Hydrology; M.d. Pereira, Centre for Ecology and Hydrology / Lancaster; J.P. Sumpter, Brunel University / Institute of Environment Health and Societies
The aim of this project was to identify which of the many chemicals we contaminate the natural environment with are likely to be causing the greatest harm. Whilst this may at first seem obvious, the reality is that environmental science can be pushed in many directions with actual risk not being the sole criterion for the research. In this exercise the focus was on chemicals subject to chronic discharge from the human population, rather than those more associated with spill accidents, or chemicals discharged from a particular industry in a discrete location. The 73 chemicals studied in detail included metals, pharmaceuticals, persistent organic pollutants (POPs), pesticides, biocides, surfactants, plasticisers and nanoparticles. For each class, selected representatives were studied in detail to hopefully act as a guide to the risk of that group as a whole. The principle of the data collection was to be representative of the spread of species and effects reported. Typically around 50-100 effect data points and 50-100 measured data points were used. What stands out from the results is the magnitude of the differences in risks between the chemicals. So for example Zinc based on its toxicity and dissolved river concentration would appear to represent a 10,000-fold greater risk to UK rivers than say nano-silver or propranalol and 100,000-fold greater risk than metoprolol! Using different refinements such as only using recent UK water measurements, dissolved concentrations, lethal or sub-lethal effects and only those compounds with BCFs higher than a 1000 still led to metals such as zinc and copper dominating the top 10 risk.

558
Estimating emissions, concentrations and combined effects of REACH substances in EU waters

In this contribution, we present the analysis of the emissions, exposure and net expected mixture impacts from 4000+ monoconstituent organic chemicals, registered under REACH up til February 2015. A train of models was used to describe, predict and analyze potential impacts of REACH chemicals in aquatic ecosystems. Starting from registered EU tonnages, emission rates to an imaginary downstream local EU-environment consisting of air, water and soil were estimated by means of a newly developed, REACH-based release estimation model which accounts for all major use stages and known usages during the substance Life Cycle. In a subsequent fate modeling step, a simple unit-world fate model, combined an STP model were used to predict steady-state masses in air, water and soil. In a final calculation step, expected impacts of the REACH chemicals to aquatic ecosystems were estimated using SSD-based hybrid toxic pressure calculation. Derived emission rates, expected environmental concentrations and predicted impacts on an imaginary EU freshwater ecosystem were compared with results of water quality monitoring programs, such as the third Joint Danube Survey (JDS3). Total market volume of REACH-registered 'mono constituent organics' amounted to $2x10^8$ ton/yr in 2015. Emission rates vary strongly among usages; it is estimated that typically near 25% of the marketed volume is released at some point during the chemical's life cycle. Predicted exposure concentrations in an imaginary EU fresh water body range from less than 1 fg/L to nearly 1 mg/L. Potentially Affected Fractions of species that result from such exposures range from practically zero as much as 10%. Toxic pressures from individual substances are usually very low. However, occurrence of high toxic pressures from individual chemicals at specific locations, although often highly uncertain, cannot be ruled out. The combined exposure to mixtures of chemicals is expected to result in undesired toxic pressures at many places, particularly so in downstream parts of river catchments. Emission, fate and impact-oriented modeling helps to identify priority mixtures and drivers of mixture toxicity, which are important steps towards the definition of River Basin Specific Pollutants and the revision of priority pollutant lists.

Spatially and temporally resolved exposure modeling with STREAM-EU: Prediction of environmental concentrations of multiple industrial compounds in European river basins
C. Lindim, Stockholm University / Department of Environmental Science and Analytical Chemistry ACES; J. van Gils, DELTARES; I. Cousins, Stockholm University / Department of Environmental Science and Analytical Chemistry ACES; D. Georgieva, Laboratory of Mathematical Chemistry / Laboratory of Mathematical Chemistry; R. Kühne, Helmholtz Centre for Environmental Research UFZ; D. van de Meent, RIVM / DMG
The Water Framework Directive (EC, 2000) aimed at achieving good ecological status in European water bodies by 2015. But currently good ecological status occurs in less than half of the European freshwater bodies, with a large proportion of them having an unknown status due to insufficient monitoring. Ecological degradation of water bodies is often caused by pollution from the thousands of commercially available chemicals that are widespread in the environment. Knowledge about the environmental occurrence of these chemicals is in many cases lacking despite being of great relevance. Appropriate estimates of environmental concentrations can be obtained using models. However, existing large-scale models have only been applied to simulate down-the-drain chemicals and are not applicable to some of the substances in use. Within the EU-FP7 project SOLUTIONS the challenge was addressed by developing STREAM-EU (Spatially and Temporally Resolved Exposure Assessment Model for European basins), a large-scale fate and transport model able to simulate spatially and temporally resolved environmental concentrations of any organic substance in all relevant environmental media. In the current work, STREAM-EU was used to simulate environmental concentrations of multiple industrial compounds subject to REACH (EC, 2006) registration in European river basins.\nThe simulated industrial chemicals were selected from priority pollutant lists and cover a broad range of uses, functional groups and toxicological effects. An assessment of the predicted exposures was done by comparing monitored and simulated bulk concentrations using field data from the Joint Danube Survey 3 (JDS3) with a reasonable agreement found between model estimates and measurements.\nOur newly developed model constitutes a large step towards wider understanding and quantification of industrial chemicals' exposure. Its applicability to any type of organic substance, any European catchment and both diffuse and point source pollutants makes it invaluable, for example, to perform large-scale human and ecological risk assessments, evaluate and choose abatement options and prioritize pollutants. All of these model applications, among others, are planned within the SOLUTIONS project.

Kuemmerer, Leuphana University Lüneburg / Institute of Sustainable and Environmental Chemistry; A. van Wezel, KWR Watercycle Research Institute / Chemical Water Quality and Health
Patterns of pollution in river basins change with time. Management strategies should address such developments. Many scenarios are published which describe future changes in society: climate change, demographic change, urbanization and others. Specific trends can be predicted (with uncertainties) already now. Does this help to get a picture on future pollutants? In most of the existing scenarios, impacts on (aquatic) ecosystems are not directly addressed. However, scenarios often describe trends which can be linked to the use of chemicals. Therefore, they can be the starting point to analyse implications on future use and emissions of chemicals and consider how to anticipate in terms of risk prevention.
Sector-specific trends have been analysed with a wide range of experts from the respective sectors with focus on health care, food production and supply, urbanization and changes in land use and new technologies. It could be shown that these developments have many and often complex implications on future pollutants. Patterns of use will change e.g. for pharmaceuticals, biocides, household chemicals as well as for specific groups of industrial chemicals. In many areas legacy chemicals will contribute significantly to the future impact on the environment – besides really unexpected new substances. This refers not only to substances which have been used in society decades ago and are still present in the environment or in "stocks", e.g. buildings, so called legacy chemicals. It refers also to a large number of "new materials", which are often based on the use of already existing chemicals in processes or technologies for which they were not originally conceived. Furthermore, completely new molecules and materials have to be expected with not yet known usage, field of application and properties and transformation products. Some of the future trends can be integrated in exposure and risk modelling. Examples are predictions on demographic change and changes in the consumption pattern of pharmaceuticals during life time. Other trends can have implications for effect monitoring. The expected increase of emissions of pharmaceuticals could stimulate the development of drug-specific monitoring endpoints, e.g. behavioural changes in fish. These findings will be used in the project SOLUTIONS to develop prioritization and risk reduction approaches for individual chemicals and mixtures and for assessment of abatement and policy options

Identifying and regulating PBT and vPvB chemicals: Requirements,challenges and policy implications

561
Comparison of P, B and T properties of parasiticides and harmonisation of the basis for an environmental assessment at the EU level
J. Roembke, K. Duis, P. Egeler, D. Gilberg, C. Schuh, ECT Oekotoxikologie GmbH; D. Hennecke, Fraunhofer IME - Institute for Molecular Biology and Applied Ecology / Ecological chemistry; M. Herrchen, Fraunhofer IME Institute for Molecular Biology and Applied Ecology; L.E. Hölzle, University of Hohenheim; B. Heilmann-Thudium, University Hohenheim; R. Düring, Justus Liebig University Giessen / Institute of Soil Science and Soil Conservation; M. Wohde, J. Behn, University of Giessen; N. Adler, UBA FG IV 2.2 Arzneimittel
Persistent, bioaccumulative and toxic (PBT) substances are of specific concern and their identification is part of various regulations. The environmental risk assessment of veterinary pharmaceuticals includes a PBT screening and, if required, a PBT assessment for the active substances. However, so far it is not clear how PBT properties should be considered in the risk/benefit evaluation of veterinary pharmaceuticals, and which consequences the classification of an active substance as PBT might have. Furthermore, there is no complete and consistent database for a comparative assessment of P, B and T properties of different parasiticides. The present project contributes to filling these data gaps by deriving octanol/water partition coefficients and fish bioconcentration factors for selected parasiticides, and by compiling available data on the excretion of parasiticides by pasture animals and on their effects on dung organisms. Octanol/water partition coefficients (P_{ow}) for ivermectin (log P_{ow}: 5.6) and selamectin (log P_{ow}: 6.0) as determined with the slow-stirring method (OECD test guideline 123) are higher than previously available values. Bioconcentration of ivermectin in zebrafish (*Danio rerio*) is currently investigated according to OECD test guideline 305. First results indicate that a steady state is reached relatively fast. In a second test, bioconcentration of doramectin will be studied. Based on the evaluated literature data the toxicity of parasiticides to dung organisms can be classified as follows: doramectin > ivermectin ≈ eprinomectin > moxidectin. The obtained results will be used to identify effective and feasible risk management measures for parasiticides with PBT properties that will be discussed with competent authorities, veterinarians and farmers.

The Origin and Evolution of Persistence Criteria for PBT Chemicals and Persistent Organic Pollutants
M. Matthies, University of Osnabrueck / Institute of Environmental Research; K.R. Solomon, University of Guelph / School of Environmental Sciences; M. Vighi, IMDEA Water Institute / Earth and Environmental Sciences; A. Gilman, Sustainable Solutions International; J. Tarazona, European Food Safety Authority / Pesticides Unit
Public concern over the effects of persistent chemicals began in the early 1960s. Since then, significant scientific advances have increased our understanding of persistent, bioacumulative, and toxic (PBT) chemicals and the properties and processes that influence their fates in, and adverse effects on, humans and the environment. In addition to the scientific advances, a number of legal instruments and agreements for global, international, and national identification and control of persistent organic pollutants (POP) and PBT chemicals have been adopted. However, some of the rationales and thoughts that were relied upon when the first criteria were developed to identify and categorize PBT chemicals and POPs have not been carried forward. Criteria for identification of persistent chemicals are single-media half-lives based upon available data for neutral hydrophobic “reference chemicals”, derived under laboratory conditions, and consensus-based policy decisions. Criteria have evolved over the last decades due to the diversification of the protection aims under various national regulatory frameworks and international agreements, advances in methods for estimation of physical/chemical properties, and the identification of chemicals which are non-traditional POPs. The numerical criteria serve as ‘yardsticks’ for assessing persistence properties of POPs and PBTs. From a scientific perspective, it is logical to use the same reference conditions as were defined for setting criteria values, when assessing a substance under review. If conditions, e.g. temperature or organic matter content, are changed for the determination of the properties of a substance undergoing assessment, the comparison may no longer apply. A better understanding of the robustness of persistence indicators, in particular for water-sediment systems, and a consensus on the interpretation of non-extractable residues in soil and sediment, would improve the persistence criteria for screening and classification. Setting appropriate numerical criteria for P_{ov} would ensure that environmental contamination is reduced in a reasonable time frame. Weight of evidence should be applied in developing these revisions. Matthies M, Solomon K, Vighi M, Gilman A, Tarazona J. The Origin and Evolution of Assessment Criteria for Persistent, Bioaccumulative and Toxic (PBT) Chemicals and Persistent Organic Pollutants. Integrated Environmental Assessment and Management (accepted).

563
Use of monitoring data to assess PBT, vPvB and POP properties of chemicals
B. Baensch-Baltruschat, Federal Institute of Hydrology / Radiology and Water Monitoring; K. Duis, ECT Oekotoxikologie GmbH; C. Rauert, Umweltbundesamt / International Chemicals Management; H. Ruedel, Fraunhofer IME - Institute for Molecular Biology and Applied Ecology / Environmental Monitoring; M. Keller, Federal Institute of Hydrology / Radiology and Water Monitoring
Environmental risk assessments regarding PBT, vPvB and POP properties of chemical substances are mainly based on modelling and laboratory data. However, both the current ECHA guidance and the Stockholm Convention include the additional use of monitoring data to assess these properties. For instance, according to the ECHA guidance findings of significant concentrations of a substance in remote and pristine environments may provide evidence of long-range transport potential (LRTP) and high persistence. Significant concentrations of a chemical in higher levels of the food chain in unpolluted areas are also regarded as an indicator of high persistence besides bioaccumulation. In the Stockholm Convention monitoring data from remote regions, esp. detection in the Arctic/Antarctic, are regarded as crucial information on the LRTP of a chemical. If sufficient data on production and usage volumes, and/or emissions of a substance are available, a more comprehensive assessment is possible including, e.g. temporal trends of contaminations. In a recent project the options of using monitoring data to assess persistence, bioaccumulation and LRTP of 6 (potential) PBT substances were tested. Data were compiled from monitoring programmes operated in Germany or with German participation and supplemented by monitoring data from other European countries and the Arctic Monitoring and Assessment Programme. In a second project, detection of substances in the Arctic/Antarctic was used to identify potential POP candidates in the context of the Stockholm Convention. Monitoring data and other relevant information were also compiled to confirm the assessment of new POP candidates, which had been prioritised based on modelling data. The results show that, besides prioritisation based on modelling data, detection of substances in remote regions can be used to identify potential POP candidates. For both approaches additional data are required to confirm substance prioritisation. Furthermore, monitoring data are an essential information to support PBT or POP assessments based on modelling and laboratory data. This is especially true for LRTP for which laboratory data are hardly available. Appropriate monitoring data tailored to specific issues referring to persistence, bioaccumulation and biomagnification in food webs are currently accessible for few substances only. Thus, such monitoring studies are esp. recommended if modelling and laboratory studies yielded insufficient results.

564
Screening and prioritization of chemicals for PBT behavior: state of the art on the consensus approach by PBT Index and PBT Profiler
A. Sangion, S. Cassani, University of Insubria / DiSTA; E. Papa, Department of Theoretical and Applied Sciences; P. Gramatica, University of Insubria / DiSTA
The limited availability of comprehensive data to describe Persistence, Bioaccumulation and Toxicity (PBT) properties pose a serious hindrance to the categorization of chemicals as PBTs or vPvBs, which use is regulated in REACH through authorization and additional plans for safer alternatives. A possible solution to this problem is the use of *in silico* approaches, such as those based on QSARs, which are valid alternatives to animal testing. These approaches generate predicted data and help in early identification of chemicals of high concern and in the definition of priority lists. In the context of screening and prioritization tools for PBT-assessment, we proposed a screening method founded on a consensus approach between two different QSAR-based models for the identification of PBTs. We developed this approach by combining predictions generated by the Insubria PBT Index model, implemented in the QSARINS software (which we developed at University of Insubria), with those calculated by the US EPA PBT Profiler, a freely available online tool for the preliminary PBT screening of organic chemicals. Predictions which were in agreement between the two models were more consistent, reliable and with a higher probability to correctly identify PBT chemicals, than those generated by one of the two models taken singularly. During the last years, we have applied this consensus approach to screen and prioritize big datasets of chemicals of environmental concern with heterogeneous molecular structure, and to screen specific groups of chemicals such as Flame Retardants, Personal Care Products and Pharmaceuticals. The good agreement between the two models, supports the utility of the consensus approach to highlight the need for urgent experimental tests on compounds prioritized in agreement as PBTs. The screening case sudies, described in this presentation, are examples of how results generated by the Insubria PBT Index and by the US-EPA PBT profiler, which are both based on chemical structure, can be combined in order to identify the most dangerous among the studied compounds. It is evident that the reliability of the predictions is higher for compounds that are predicted in agreement by different methods. The consensus approach combines the perspectives given by multiple modelling methods, which are based on different structural features and mathematical approaches, and is useful to integrate PBT/vPvB assessment procedures based on thresholds criteria.

565
Regulatory PBT/vPvB assessment of UVCB-substances
I. Doyle, Environment Agency / Evidence Directorate; J.R. Peltola-Thies, ECHA-European Chemicals Agency; J. Caley, European Chemicals Agency - ECHA / Evaluation; P. Lepper, European Chemicals Agency ECHA; L. Walker, European Chemical Agency ECHA

The experience in assessment of PBT/vPvB properties of substances of Unknown or Variable Composition or Biological origin (UVCB-substances or UVCBs) has increased considerably in recent years. During the last four years alone over 50 UVCB-substances were assessed for their PBT/vPvB properties by REACH competent authorities in Europe. Furthermore, a very high number of UVCBs have been assessed by REACH registrants so far. Generally, it is necessary to assess the PBT properties of all relevant constituents of a substance. However, due to their complexity and variable nature, accurate assessment and testing of all individual UVCB constituents is often not technically feasible or resource and cost-effective. Efficient assessment and testing strategies are therefore essential. The following pragmatic approaches have been applied to date: (1) Whole substance approach; (2) Fraction profiling approaches; (3) Known worst case constituent approach; (4) a combination of one or more of these three approaches. This presentation explains the approaches and gives an overview of their application with a few examples : MCCPs, styrenated phenol, coal tar pitch, high temperature, polybrominated diphenyl ethers and *tert*-dodecylmercaptan.

566
How to apply socio-economic analysis to REACH-authorisations of PBT and vPvB chemicals? A critical synopsis of approaches and decision-criteria
S. Gabbert, Wageningen University / Social Sciences; I. Hilber, Agroscope ART; M. Nendza, Analytisches Laboratorium AL-Luhnstedt; O. Warwick, Peter Fisk Associates Limited
A core aim of the European chemicals legislation REACH is to ensure that the risks caused by substances of very high concern (SVHC) are properly controlled. Authorisation – i.e. the formal approval of certain uses of SVHC for a limited time - is a key regulatory instrument in order to achieve this goal. For persistent, bioaccumulative and toxic (PBT) or very persistent and very bioaccumulative (vPvB) SVHC listed on Annex XIV of REACH, decision-making on the authorisation is conditional on a socio-economic analysis (SEA), in which companies must demonstrate that the gains from keeping a chemical in use outweigh expected damage costs for society. The current setup of the REACH authorisation process, however, raises a number of questions concerning the practical applicability of this tool. We suggest a tiered framework for which we discuss key analytic steps and informational requirements which we consider crucial in order to operationalise SEA of PBT and vPvB chemicals. Using the case of hexabromocyclododecane (HBCDD), an Annex XIV PBT substance which had a sunset (phase-out) date in August 2015, we investigate key challenges that need to be met in order to ensure that a SEA can be operationalised in a meaningful way. We illustrate that, if monetary estimates for health and environmental impacts are available (e.g. from impact-specific valuation studies), a SEA will deliver the optimal period of use of a chemical. Thus, an authorisation should be granted with a review period that extends until marginal discounted benefits of use equal marginal discounted damage costs. A crucial aspect of this path is the selection of a concern-based discount rate. Another challenge is to examine the use of environmental monitoring data for determining media-specific impact functions. However, a monetary impact valuation is unlikely to be feasible for most PBT chemicals. Still, if sufficiently reliable information on a chemicals' toxicity is available, non-monetary evaluation approaches, for example multi-criteria or cost-effectiveness analysis, can be applied in a SEA. For vPvB chemicals, in particular, a SEA applying (explicitly or implicitly) efficiency decision-criteria turns out to be inappropriate because of deep uncertainty regarding vPvB's toxicity and risks. We therefore suggest to adopt an alternative authorisation route for vPvB chemicals, which should be based on robustness criteria such as, for example, the 'minimisation of maximum regret'.

How can we improve the link between academic research and policy-making in order to advance chemical risk assessment and management?

567
CRED - Criteria for Reporting and Evaluating ecotoxicity Data
C. Moermond, RIVM / Centre for Safety of Substances and Products; R. Kase, Swiss Centre for Applied Ecotoxicology EAWAG - EPF; M. Korkaric, Swiss Centre for Applied Ecotoxicology, EAWAG-EPFL; M. Agerstrand, Stockholm University / Environmental Science and Analytical Chemistry
The derivation of safe concentrations of chemicals for ecosystems, such as Predicted No Effect Concentrations (PNECs) or environmental quality standards (EQSs), is an important aspect in a large number of (legal) frameworks worldwide. Different datasets are used in the various frameworks, and combined with the use of different assessment methodologies this often leads to the derivation of different PNECs/EQSs for the same compound. However, even when the same set of study reports and/or references from the open literature is available and the same guidance documents are used, there is no guarantee that risk assessors will arrive at the same list of usable endpoints from these studies. The evaluation of scientific reliability and relevance of ecotoxicity studies is often subject to expert judgment, and results may differ between frameworks and between assessors within one framework. To improve the evaluation of aquatic toxicity studies, the CRED project was started. CRED stands for Criteria for Reporting and Evaluating ecotoxicity Data. The aim of CRED was to improve the reproducibility, transparency and consistency of reliability and relevance evaluations amongst frameworks, countries, institutes and individual assessors. We also aim to improve the usability of peer-reviewed literature for substance evaluations, and in the end improve the exchange of assessment results between frameworks. We will present the CRED method, which includes a set of 20 reliability and 13 relevance criteria with an extensive guidance, as well as a guidance on how to report data from ecotoxicity studies. To test the applicability of the methodology, we performed a ring test with over 80 risk assessors from Europe, Asia and North America, representing academia, regulatory agencies, consultancies and industry. Ring test participants evaluated the CRED evaluation method to be more accurate, applicable, consistent and transparent than the often-used Klimisch method. The CRED evaluation method is accompanied by reporting recommendations for aquatic ecotoxicity studies, with 50 specific criteria divided into six categories: general information, test design, test substance, test organism, exposure conditions, and statistical design and biological response. An ecotoxicity study in which all important information is reported is more likely to be considered for regulatory use, and proper reporting will support the peer-review process.

568
Lessons learned from a multi-country project under the SAICM Quick Start Programme
M. Scheringer, ETH Zurich / Institute for Chemical and Bioengineering; C.A. Ng, ETH Zurich / University of Pittsburgh; C. Bogdal, Institute for Chemical and Bioengineering ETH Zürich / Institute for Chemical and Bioengineering; A. Bergman, Stockholm University; H. Fiedler, Orebro University; A. Aleksandryan, Hazardous Substances & Waste Policy Division / Head of Division; A. Khachatryan, Waste Research Center; R.O. Barra, Universidad de concepcion / Aquatic systems; C. Gallardo, Ministry of the Environment; S. Adu-Kumi, Environmental Protection Agency; J. Pwamang, Ghana EPA
Under the SAICM Quick Start Programme, a multi-country project on "Training on risk assessment for chemicals at national level in a global context" was implemented by the governments of Armenia, Chile, and Ghana in the period of 2010–2014. The International Panel on Chemical Pollution, IPCP, was the executing agency of the project. The overall aim of the project was to make available, in each of the three countries, a set of methods, tools and data for chemical risk assessment ("materials") and to conduct workshops and national training activities that enable scientists, government representatives and other stakeholders to access and use these materials. In the initial phase of the project, a kickoff meeting with representatives of all countries, IPCP scientists, and experts from international organizations (WHO, OECD) as well as national workshops in each of the countries were conducted. This was followed by a phase of national case-study work (case-study topics were PCBs and organochlorine pesticides in Armenia, heavy metals in Chile, atrazine in Ghana) in collaboration with IPCP scientists and international experts. Finally, the results obtained were collected, discussed and compared at a synthesis workshop at the end of the project. The project required coordination of partners from several different types of institutions: government institutions in each of the countries; a range of national stakeholders such as national research institutes, NGOs, universities, and industry associations; experts from international organizations, IPCP scientists, and the SAICM secretariat. Important conclusions from the project are: (i) Methods for first approximations or estimates of the components of a chemical risk assessment, such as emission rates of a chemical, were found to be useful and of immediate benefit. (ii) Approaches that enable project participants to establish a "big-picture" understanding are important because often there is an extensive body of data from various projects available in a country. Offering a framework that can accommodate existing data helps reconcile existing data and supports long-term thinking and collaboration of experts from different fields. (iii) More time than anticipated may be needed because local stakeholders, interest groups, and societal actors need to be involved; it is not easy to estimate in advance how much time will be needed for this process and what the outcomes of the local stakeholder discussions will be.

569
Using the ecosystem services framework to link scientific research and policy-making: a case study of Lake Tai, China
Y. Pan, University of Sheffield / Animal and Plant Sciences; L. Maltby, The University of Sheffield / Dpt of Animal Plant Sciences
One way of linking scientific research and policy-making is to increase public participation into decision making processes, because public perceptions can play a significant role in identifying protection goals for use in chemical risk assessments. One approach to forming protection goals is to identify ecosystem services (i.e. benefits that we obtain from ecosystems) valued by society. Different sections of society may not have the same ecosystem values and this should be considered during the establishment of protection goals. Clear protection goals are vital for many developing countries with rising economies, such as China, which suffer from unsustainable development and environmental degradation. The aim of this study was to investigate the value of ecosystem services to local communities using Lake Tai, China, as a case study. Lake Tai is the third largest

freshwater lake in China and is affected by severe anthropogenic threats, including chemical pollution that can negatively impact ecosystem services. Four cities surrounding the lake were investigated by conducting interviews with 255 rural and 252 urban respondents. There are similarities and differences between the value of services across cities, as well as across rural and urban communities. Each group of respondents ranked freshwater provision as the most important service but other services were valued differently between respondents situated at different locations around the lake. Rural communities ranked directly-used services (i.e. food provision and flood regulation) higher than urban communities, who ranked indirectly-used services (i.e. cultural services) higher. Prioritised services can be adversely impacted by chemical pollution in Lake Tai and 40% of the respondents were concerned about water pollution. By identifying services prioritised by the public, we can then identify drivers that support the services and specify protection goals. This study sets out a framework for investigating the ecosystem values of different communities. In addition, it highlights the question of how protection goals should be set when different sections of society have varying ecosystem values. By using the ecosystem services framework, this study has linked scientific research, social sciences and policy-making.

570

Use of the SEA and DSFA in risk assessment and management for chemicals of concern

J. Liu, Peking University; L. Li, Peking University / College of Environmental Science and Engineering; R. Weber, POPs Environmental Consulting; J. Zhu, Peking University

To alarm inapprehensive upcoming concerns so as to avoid them beforehand is granted as the ultimate goal of risk management and communication. This goal necessitates comprehensive, systematic appraisal of possible adverse impacts with a holistic consideration of social, economic and environmental impacts on a long-term temporal scale before decision making. Here we propose that a cost-effectiveness-oriented socio-economic assessment (SEA) framework, coupling with a dynamic substance flow analysis (DSFA), is competent for such appraisal in national management of hazardous chemicals to implement multilateral environmental agreements. We exemplified the application of the two approaches using the case of phasing out hexabromocyclododecane (HBCDD) in China. The SEA results indicate that the schedule of phasing out HBCDD production and new uses within two five-year exemption periods generates higher environmental and health benefits while that within a five-year exemption period leads to smaller economic and social costs. A decision can be biased if we ignore the environmental and health benefits and their related positive externalities. The DSFA results show that a whole century or longer time will be needed to eradicate HBCDD from the present in-use and waste stocks although production and new uses will stop soon. Therefore, future management efforts should be devoted to end-of-life disposal management. Our case highlights the implication and importance of the SEA and DSFA in national chemical management and risk communication.

571

Participative valuation of ecosystem services of aquatic ecosystems: Evrotas river basin Greece

P. Ker Rault, J. Luttik, Alterra

Little is known beyond the described effects of single stressors on the chemical and ecological status of water bodies and on their ecosystem functionality. This lack of knowledge limits our capacity to understand ecosystem responses to multiple stressors and to define a programme of measures that can improve the ecological status of a water body as sought by the European Water Framework Directive. The ecosystem services framework aims to support informed decision making by explicitly linking the goods and services produced by functioning ecosystems to human well-being illustrating the broad impacts of various land-use scenarios. The Economics of Ecosystems and Biodiversity (TEEB) approach provides a framework for assessing multiple stressor and multiple outputs of a river basin, facilitating management of a complex system. Economic valuation includes monetary and non-monetary methods. Monetary methods although under continuous development and construction are well documented [3], [4], [2]. Non-monetary valuation relies on perception and values of stakeholder at large. The main research question addressed is: How do stakeholders perceive Ecosystem services and functioning at river basing level? The practical framework to elicit stakeholder knowledge and to enable discussion around the functioning of Ecosystem services is based on a participative workshop with representatives from the public and private sector involved in water management, nature management, cultural heritage and water related economic activities, municipal, and regional planning. A brief presentation of Ecosystem definition and types was given in order to provide the participant with the same conceptual framework and basic knowledge of TEEB. Group-dynamic was rhythmed by group exercises, restitution of group findings in plenary session enabling expression of view-points and social learning. The core activity of the workshops is co-construction of ecosystem services, in three steps: (i) identification of ecosystem services in groups of four to six participants, (ii) plenary exchange of the findings, in order to identify the major ecosystem services, made specific for the river basin and (iii) individual ranking of ecosystem services by participants. The case study is the Evrotas river basin in Greece, 25 valid questionnaires were collected and analysed.

Challenges in data analysis, weighting, valuation and visualisation - How to enable decision makers to make trade-offs while being transparent for all stakeholders

572

Combining Fuzzy sets with LCA to weight global environmental impacts with local limits of ecosystem capacity

F. Dinkel, Carbotech AG; C. Stettler, Carotech AG; F. Conte, T. Kaegi, Carbotech AG

Small hydropower plants (SHP) are discussed very controversially. They are essential for the realization of the Swiss Energy Strategy 2050 and looking at the impacts like climate change, energy demand or emissions SHP belong to the most eco-friendly power plants. However they can have relevant impacts on flora, fauna and the local ecosystems and these impacts are specific to each location. An overall weighting taking into account the relevant impacts and local aspects of ecosystems capacity is crucial for a decision support. The goal of this project is to build an evaluation tool for SHP, taking into account all the different environmental impacts, local tipping points and economic aspects. So the challenges are: To combine quantitative indicators e.g. from LCA with qualitative criteria on the local ecosystems. Taking into account the limits and capacities of the local ecosystems. Expressing the expert knowledge on the relation of different factors and ecosystem capacity even if they are controversy. To get a cost efficient method to be applied at SHP projects with limited budgets. After discussions with a variety of experts and studied different evaluation methods it become clear that for modelling expert knowledge given in quantitative as well as in linguistic terms the best method is fuzzy set theory (FST). This method gives the possibility to weight the different LCA results, to introduce qualitative expert judgment and furthermore different even contradictory judgments to be taken into account in the same model. A group of experts from different fields like hydrologist, biologists, from NGOs, administrations, technicians and LCA specialists has been formed to build the model. The first evaluation has shown promising results but further improvements are necessary. The experience from evaluation and modelling has shown that this method is very suitable to evaluate complex systems like ecosystems, taking also into account their capacity. The important advantages of this method are: representation of qualitative expert knowledge with linguistic terms bringing together in a mathematically exact way quantitative and qualitative data and knowledge nonlinear relations can be handled and FST makes the interpolation floating transitions which are typical for environment can be handled FST can give more than one 'right' result typical for human reasoning. Doing all this in a transparent way.

573

Reversibility assessment: how to improve the weighting of impacts in LCA

S. Sala, European Commission - Joint Research Centre / Sustainability Assessment unit; J. Pasqualini, University of Milano Bicocca; M. Vighi, Fundacion IMDEA Agua

Weighting impact categories in LCA is an optional step according to ISO14040. However, in the context of LCA in support to policy, weighting may help in the: i) identification of the most relevant impact categories, i.e. to define Product Category Rules (PCRs) for product labelling (as in the case of Product Environmental Footprint – PEF – of products (EC, 2013); ii) to address eco-innovation policies and strategies towards the most effective solutions for decoupling impacts from production; iii) presenting results as a single score. Currently, the ILCD recommandations for life cycle assessment (EC-JRC, 2011) as used in the product environmental footprint (PEF) (EC, 2013) entail 15 impact categories at midpoint. The identification of the most important impact categories at the moment is done adopting a 1:1:1: weighting. Over the years, several weighting set has been proposed in literature (see a recent overview in Itsubo, 2015) such as: proxy methods, midpoint or endpoint methods following different approaches such as e.g. distance to target, monetisation, panel- based sets etc. However, all those methods present stenghts and limitations among which the capability of assessing the environmental relevance of the impacts from a sustainability point of view. The present work aim at discussing to which extent sustainability principles, such as the avoidance of irreversible impacts (see e.g. NRC, 1999), could be a criteria for determining the relative weight of an impact category. Some qualitative attempts have been made (e.g. Soares et al 2006, including the topic amongst criteria for weighting), proposing to a panel of expert to judge the degree of reversibility with a 5-levels score systems spanning from: a natural istantaneus reversibility, to a soley artificial up to irreversible. Moreover, Fanai and Burn 1997 listed specified characteristics of some impacts and direct measures of the severity of other impacts to be used in a “distance metric” formulation to evaluate a reversibility index. A case study on the reversibility of lake eutrophication is reported to discuss potential and limitation in using reversibility as a criteria for weighting. The results stem from the analysis of the evolution of the state of a lake over time, at decreasing environmental pressure in term of human induced nutrient’s loads.

LCA single score results about PCB-contaminated sediment disposal options lead to reassessment of authorities' decision

E. Franov, T. Kägi, Carbotech AG

The Klingnau reservoirs main problem today is the silting of the lake. Dredging is being considered to extract the sediments. The dredged sediment can be disposed of by resuspension into the river or by disposal in a land fill. Article 40 states that resuspension can be considered as an option if the flora and fauna downstream is not negatively affected. As the sediment of the Klingnau reservoir is contaminated with pollutants such as heavy metals and PCBs, a qualitative environmental impact assessment commissioned by the authorities was carried out. The concentrations were below the maximum permissible values and indicated that no negative effects were expected by resuspending the sediments. The assessment showed on the other hand that the emissions of the disposal to a land fill option would exceed the maximum permissible values of the Swiss "Clean Air Act for Construction Transports". The environmental impact assessment concluded that the resuspension of the sediments to the river has a lower environmental impact than their disposal to a land fill. In order to verify the results of the environmental impact assessment, the two options were analysed by Life Cycle Assessment. The LCA shows very clearly that the disposal of the dredged sediment by resuspension into the river has a much higher environmental impact than the disposal in a landfill. This is mainly due to the PCB and heavy metal contents in the sediment which in case of the resuspension option affects the river ecosystems negatively. This example shows how important it is to perform a comprehensive assessment in order to evaluate the environmental consequences. The consequence of the LCA results for the Klingnau reservoir dredging project was that the planned resuspension of the dredged sediments to the river was discarded and the concept is currently being revised. As it has been shown in this paper it can prevent severe misjudgements compared to decisions that are only based on legal limits for single pollutant emissions. The presentation of single score LCA results plays an important role in the process of persuading decision makers to change their mind for an environmentally preferable option as such results usually are clear and easily understandable because they don't need further interpretation.

How far can changes in consumer behaviour take us on the path to environmental sustainability?

A. Bjorn, Technical University of Denmark / Department of Management Engineering; P. Kalbar, Technical University of Denmark; S.E. Nygaard, Aarhus University; M. Hauschild, DTU Management Engineering / DTU Management Engineering; M. Birkved, Technical University of Denmark / QSA Dept of Management Engg

It has recently been proposed to normalise environmental impacts according to environmental carrying capacity in LCA, to arrive at normalised indicator scores expressed as occupations of carrying capacity. This can facilitate the evaluation of whether a studied anthropogenic system is environmentally sustainable. This study presents the first application of carrying capacity based normalisation to a real-life comprehensive case study. The case study aims to covers the total annual consumption of goods and services of 1283 urban Danes, based on their response to a lifestyle survey. The goal of this study is to demonstrate the applicability of carrying capacity based normalisation by exploring the extent to which Danes can become environmentally sustainable by practical changes in behavior. The LCIs of total personal consumption were compiled by combining process-based inventory modelling (e.g. for consumption of food and residential heat) with environmentally extended input-output analysis (e.g. for expenditures on electronics and clothing) and extrapolations for other impact categories than climate change. A "minimum impact"-profile was constructed by combining the environmentally soundest qualitative and quantitative consumption behaviour observed in the respondent pool across consumption categories, while disregarding potentially erroneous outliers having unrealistically low consumption values. The average respondent was found to exceed his or her fair share of carrying capacity for five impact categories. For climate change and photochemical ozone formation the exceedance was above a factor of 10. According to the results, the average respondent would be able to decrease his or her impact by 25-50% if he or she adopted the behaviour of the minimum impact-profile. Yet, the minimum impact-profile was found to be environmentally unsustainable for five impact categories, albeit less so than the average profile. The case study results indicate that (quite large) behavioural changes alone are insufficient for achieving the goal of personal environmental sustainability for all LCA impact categories in a Danish setting and must be supplemented by policies targeting, for example, eco-efficiency improvements of the energy system and public services. The application of carrying capacity based normalisation references in this study demonstrates that LCA, in principle, can be expanded from answering "which is better?" to also answering "is better good enough?"

Incorporating Lifecycle Thinking in Nanotechnology Risk Control and Sustainability Assessment: The Case of Sustainable Nanotechnology Decision Support System

v. subramanian, Ca Foscari University of Venice / Dept of Environmental Sciences Informatics and Statistics; E. Semenzin, Ca Foscari University of Venice / Department of Environmental Sciences Informatics and Statistics; D. Hristozov, Ca Foscari University of Venice; A. Zabeo; I. Malsch, Malsch TechnoValuation; E. McAlea, F. Murphy, M. Mullins, University of Limerick; T. van Harmelen, T. Ligthart, TNO; I. Linkov, US Army Engineer Research and Development Center; A. Marcomini, University of Venice / Department of Environmental Sciences Informatics and Statistics

Early identification of risks and impacts of engineered nanomaterials over the lifecycle can enable stakeholders to minimize these concerns at an early stage of nano-enabled product development. The SUN Decision Support (SUNDS) system integrates tools for evaluation of the environmental, economic and social impacts of nano-enabled products, and supporting their development toward safety and sustainability. SUNDS conceptual decision framework comprises of two tiers of varying analytical complexity and data requirements. Both tiers utilize Life Cycle Thinking (LCT) and organize the most outputs of individual modules and sub-modules in terms of hotspots to be addressed through remedial measures for risk management and sustainability assessment. The first tier of SUNDS comprises of LICARA NanoSCAN, provides a semi-quantitative evaluation of the environmental, social and economic benefits and the ecological, occupational and consumer health risks of nano-enabled products from lifecycle perspective in comparison to conventional products with similar uses and functionality. SUNDS Tier 2 implements an integrated Risk Control (RC) and Socioeconomic Assessment (SEA) module, in which the RC module comprises three risk sub-modules (Ecological Risk Assessment (ERA), Public Health Risk Assessment (pHHRA) and Occupational and Consumer Human Health Risk Assessment (oHHRA and cHHRA respectively), and SEA comprises all the sub-modules (ERA and HHRA, Life Cycle Impact Assessment (LCIA), Economic Assessment (EA), Social Impact Assessment (SIA)) . Within both RC and SEA modules in SUNDS Tier 2, most of the sub-module outputs are organized within four lifecycle stages: Synthesis, Production, Use and End of Life. RC module pinpoints the hotspots for risks through the lifecycle of nano-enabled products and suggests Technological Alternatives and Risk Management Measures to appropriately reduce these risks. SEA module pinpoints hotspots for TBL impacts based on technical thresholds and user preference profiles through the lifecycle of nano-enabled products. A comparison of the number of hotspots within the lifecycle stages will pinpoint the most affected stage(s) and guide the decision-maker on where to focus remedial action. The proposed abstract discusses the benefits and methodological challenges in incorporating LCT to SUNDS conceptual decision framework, as well as insights gleaned from its application to case studies.

Harmonised decision-support and guidance in the European SPIRE programme to achieve overarching sustainability targets?

D. Kralisch, Friedrich-Schiller-University Jena / Department of Pharmaceutical Technology; A. Lapkin, University of Cambridge / Chemical Engineering and Biotechnology; M. Jones, University of Manchester / School of Chemical Engineering Analytical Science; W. De Soete, Ghent University / EnVOC

The SPIRE (Sustainable Process Industry through Resource and energy Efficiency) programme is a public-private partnership brought to life by the European Commission in the EU's research and innovation programme Horizon 2020. A financial contribution from the European Union budget of EUR 900 million is foreseen over a seven year period in order to engage eight sectors of the European process industry: chemicals, cement, ceramics, minerals, steel, non-ferrous metals, industrial water and process engineering in the development of novel technologies for improved resource and energy efficiency. By means of this measure, the ambitious SPIRE initiative (being part of the Europe 2020 strategy) aims to reduce the energy consumption in the European process industry by 30% and the utilisation of primary (non-renewable) raw materials by 20%, compared with the period of 2008 - 2011. The European project MEASURE, a coordination and supporting action within the SPIRE framework, will provide a roadmap for sustainability assessment in the European process industries and directly linked European collaborative projects, since a number of open issues (e.g. in communication, data standards, agreement on sustainability assessment methods) and R&D needs to be dealt with, before such ambitious overarching visions such as the SPIRE sustainability targets can be brought into practice in an efficient, target-oriented manner. Among the key messages of the roadmap is a broader utilization of the stage-gating approach and established decision support and project management methodologies in European funded SPIRE projects. Within a given team, the stage-gating approach could be highly effectively used as a project planning and monitoring tool, to ensure successful delivery of the key objectives against which project success will be evaluated. Consequently, the stage-gating approach should be used pragmatically to stop research activities that are less likely to contribute to the goals of the project within its lifetime. However, this requires some degree of flexibility in funding *within* the project and access to other sources of funding by research groups. To aid the pragmatic use of stage-gating, existing multi-criteria decision methodologies should be integrated into the development process to aid consistent and transparent decision making.

Contaminants of Emerging Concern in the Environment and their Management (P)

MO001
Vertical distribution of legacy and current used pesticides in marine interstitial water from eight Iberian Mediterranean areas
V. León, R. Moreno-González, Instituto Español de Oceanografia / Centro Oceanográfico de Murcia; C. Martinez-Gomez, Instituto Español de Oceanografia / Marine Contamination and Biological Effects; J.A. Campillo, Instituto Español de Oceanografia / Centro Oceanográfico de Murcia
Organochlorinated and current used pesticides (CUPs: organophosphorus, triazines and others) were determined in interstitial water of sediment cores from eight Iberian Mediterranean coastal areas (Barcelona, Tarragona, Ebro Delta, Valencia, Castellón, Cartagena, Almería and Málaga). Three sediment cores were taken at three different sampling sites per area by using a box corer at bottom depths higher than 50 m. Cores were cut into 1-cm-thick sections between 0 and 18-cm depth, interstitial water was obtained by centrifugation and samples from every site and depth were pooled. Pesticides were analyzed in interstitial water by stir bar sorptive extraction coupled to gas chromatography with mass spectrometry. Triazines, organochlorinated pesticides, organophosphorus and other pesticides were found in interstitial water of the study areas. The total number of pesticides found per each area varied from 6 to 17 compounds. Procymidone and propyzamide were found in all areas at concentrations below 100 ng L^{-1}. Other commonly detected compounds were a-endosulfan, m-parathion, alachlor, chlortal dimethyl and simetryn. Overall the concentrations of CUPs decreased with depth in the considered areas. However, the presence of some legacy pesticides, such as p,p'-DDE was mostly detected in deeper layers.

MO002
On-site large-volume solid-phase extraction device - A solution for sufficient sample volumes in comprehensive toxicological and chemical analysis of wastewater effluent
P. Välitalo; M. Krauss, Helmholtz centre for environmental research - UFZ / Effect Directed Analysis; N. Perkola, Finnish Environment Institute / Laboratory Centre; W. Brack, T. Schulze, Helmholtz centre for environmental research - UFZ / EffectDirected Analysis
Recently, more comprehensive approaches such as multi-target, non-target and bioanalytical techniques and combinations of these, have risen next to the more traditional way of monitoring hazardous compounds in wastewater effluents. However, one big issue related to extensive ecotoxicological profiling and chemical analysis is the amount of sample needed for such analysis. In addition to volume, sufficient concentration factors are needed because many of the compounds causing harmful effects are present at very low concentrations (ng/L). The main objective of this study was to apply and test the suitability of a recently developed onsite large-volume SPE device (LVSPE50) to achieve sufficient sample volumes for the comprehensive toxicological and chemical analysis of wastewater effluent. The performance of the device was evaluated by determining recoveries for selected compounds of perfluorinated alkyl acids (PFAS), hormones and bisphenol-A (BPA) from spiked artificial and real wastewater effluent by liquid chromatography mass spectrometry (LC-MS/MS). The LVSPE50 device is based on a system where the water is pumped through multiple steps through the machine (pre-filtration, sampling chamber, SPE cartridge). The device performed well with influent and effluent samples and with some WWTPs even more than 40L of sample was collected and extracted. The recoveries for PFAS were between 1-96 % and 35-109% for hormones and BPA in artificial effluent depending on the compound. Large extraction volumes made it possible to analyze the samples with multiple bioassays (FET, ER-CALUX, AR-CALUX, p53-CALUX, NRR-assay, umu-test, EROD assay) and chemical analysis of more than 400 target compounds (LC-MS/MS).

MO003
Gene expression profiling of bacteria for environmental monitoring
F.A. Khan, M. Goswami, Orebro University / SCHOOL OF SCIENCE AND TECHNOLOGY; P. Olsson, Orebro University / The Life Science Center; J. Jass, Orebro University / SCHOOL OF SCIENCE AND TECHNOLOGY
Major water pollution includes the collective discharge of domestic and industrial waste together with human bacterial pathogens into the environment. Wastewater treatment plants (WWTPs) do not completely remove all the pharmaceutical and organic contaminants, which subsequently end up in environmental waters. A major concern is that contaminants contribute to increased virulence and/or antibiotic resistance of human bacterial pathogens and thus pose a health risk to the community. We have designed and applied a gene expression system for *Pseudomonas aeruginosa* to predict the potential impact of soluble components released from sewage sludge on bacteria. *P. aeruginosa* was selected since it is both an environmental bacterium with bioremediation capacity and an opportunistic pathogen. Thirty-nine selected genes associated with stress response, virulence and antibiotic resistance were analysed by quantitative reverse transcriptase - PCR in bacteria treated with either antibiotics or heat shock for validation or sewage sludge leachates from WWTPs servicing 3 different cities (Eskilstuna, Västerås and Örebro) in Sweden. The molecular profiling of the sludge leachates from WWTPs was assessed using the principle component analysis. The sludge leachates from Eskilstuna affected a greater number of *P. aeruginosa* genes, responsible for general stress response and virulence, while Västerås sludge leachate affected fewer genes and clustered more closely to the control. Örebro sludge leachate had intermediate influence on the gene expression in *Pseudomonas*. This suggests that the presented strategy of *P. aeruginosa* toxicogenimics has potential applications in evaluating the effects of soluble contaminants on bacterial pathogens in environmental waters for considerations in risk assessment.

MO004
Pyrethroid occurrence and distribution in Brazilian fish tissues
. Aznar-Alemany, Dept of Environmental Chemistry; Ã. Rizo, IDAEA-CSIC / Dept of Environmental Chemistry; S. Nogueira, Federal University of Rio de Janeiro / Biophysics Institute; M. Alonso, Biophysics Institute, Federal University of Rio de Janeiro, Brazil / Radioisotopes lab; J. Torres, Radioisotopoes Laboratory / Environmental Biophysics; O. Malm, Fed Univ Rio de Janeiro / Biophysics Institute; E. Eljarrat, IDAEA-CSIC / Department of Environmental Chemistry; R.A. Hauser-Davis, Biodiversity PostGraduate Program; D. Barcelo, IIQAB-CSIC / Dept Environmental Chemistry
Pyrethroids are organic pollutants with high hydrophobicity used as insecticides. Concern exists about aquatic organisms' exposure to their toxicity. They produce a neurotoxic effect by altering the sodium channels of the nerve cells. Their LC_{50} values can be as low as 0.2 μg/l for aquatic macroarthropods considering a 4-day exposure, and 1 μg/l for fish. They were believed to be excreted or converted to non-toxic metabolites. But a recent work has detected them in wild river fish for the first time at significant levels in 100 % of the samples [1]. Our study investigates the occurrence of pyrethroid compounds in fish from three locations in Rio de Janeiro (Brazil), as the first attempt to determine the occurrence and distribution of pyrethroids in marine fish tissues from Brazil. This is the first study to report pyrethroid levels in wild fish tissues from the sea. Samples were collected from Rodrigo de Freitas lagoon, Ipiranga bay and Itaipu in 2009-2010, including different tissues—muscle, liver and gills—from 20 fish including 10 males and 10 females. The analytical method monitored 10 different pyrethroids. For the sample preparation lyophilized sample was spiked with internal standards, extracted by sonication and underwent a clean-up with alumina and C18 SPE cartridges. Extracts were analysed by GC-NCI-MS/MS. Method recoveries ranged 53-116 % and method LODs and LOQs were 0.02-0.46 ng/g lipid weight (lw) and 0.08-1.54 ng/g lw, respectively. Pyrethroids were detected in all the fish and most tissues. Total concentrations were in the low limit of the range found in the wild fish from Spanish rivers (12-1,508 ng/g lw) and those found in dolphins from Brazil (7.0-68 ng/g lw) [1,2]. Half of the selected analytes were detected; cypermethrin and permethrin being the main contributors to the pyrethroid profiles. *Acknowledgments* – This work has been funded by the Generalitat de Catalunya (Consolidated Research Group Water and Soil Quality Unit 2009-SGR-965). MO005
Target and non-target screening analysis using gas chromatography-quadrupole-time-of-flight (GC/Q-TOF) to prioritize emerging pollutants for seafood monitoring
S. Lee, Hanyang University; M. Choi, National Institute of Fisheries Science; H. Moon, Hanyang University / Marine Sciences and Convergent Technology
Human is exposed to organic contaminants with several pathways, depending on target contaminants and their usage. Seafood consumption has known as a major exposure pathway to toxic organic contaminants including persistent organic pollutants (POPs). In order to prioritize the emerging pollutants in seafood, we employed non-target screening analysis using gas chromatography/quadrupole-time-of-flight (GC/Q-TOF). Surface seawater, sediment, and seafood samples collected from Ulsan Bay, Korea, to investigate the occurrence and migration efficiency for detected organic contaminants. To make our analysis effective, we made database with 200 target chemical standards based on nation-wide monitoring programs (e.g. POPs). Non-target screening analysis was also performed to identify unknown chemicals in multi-media matrices. To remove matrix effect in each environmental sample, we developed

clean-up method based on solid phase extraction (SPE) with HLB cartridge. Using matching with NIST library and deconvolution techniques, we found approximately 4000 compounds in seawater, sediment and seafood samples. The predominantly identified compounds were siloxanes, phthalates, musk fragrances, and phosphate or chlorinated flame retardants, implying the strong candidates for seafood monitoring in Korean coastal waters. Our approach or framework for prioritization of emerging pollutants in seafood could be effectively utilized as occurrence-based prioritization in various environmental compartments.

MO006

Occurrence and assessment of Perfluorinated compounds in fisheries from Korea

M. Choi, I. Lee, R. Jung, National Institute of Fisheries Science

Residues of 15 perflourinated compounds (PFCs) were investigated in 58 fisheries including 31 fish from Korea. The total concentrations of PFCs in muscles of fisheries ranged from 0.04 to 32.2 ng/g wet weight. Bivalves such as mussels, oysters, and clams showed the concentrations higher than 10 ng/g wet weight. The main compounds among PFCs were perfluorooctane sulphonate (PFOS) for fish, perfluorooctanoic acid (PFOA) for crustaceans, perfluoropentanoic acid for bivalves, gastropods, and seaweeds, and perfluoroundecanoic acid for cephalopods. This suggests that bioconcentration of PFCs in marine organisms is dependent on their taxonomic features (sources of food, feeding type, and metabolism). The concentrations of PFCs in livers and intestine were greater than in muscles. The muscles of crustanceans and cephalopods had greater concentration of perfluorotridecanoic acid than intestine. We also found the difference in PFC profiles between wild fish and farmed fish. Farmed fish tended to accumulate relatively greater amounts of perfluorohexanoic acid in wild fish, while perfluorododecanoic acid was abundant in farmed fish. The calculated hazard ratio of PFCs for all fisheries muscle samples, was less than 1.0, and could be classified at safe levels for the general population. The main route of PFOS to human exposure was fish consumption, and of PFOA was crustancean consumption.

MO007

Nitrate: an Environmental Endocrine Disruptor?

R. Poulsen, University of Copenhagen / Department of Pharmacy; N. Cedergreen, University of Copenhagen / Plant and Environmental Sciences; M. Hansen, University of California, Berkeley / Civil   Environmental Engineering Integrative Biology

This poster presents a review of the increasing experimental evidence that inorganic nitrate acts as an environmental endocrine disruptor. The double Nobel Prize awarded Haber-Bosch process, which fixates atmospheric nitrogen to ammonia as a feedstock for agricultural nitrate-fertilizers, kick-started the Agricultural Revolution. Subsequently, environmental nitrogen emissions have increased tremendously. Even though nitrogen levels in surface waters during pre-industrial times cannot be precisely estimated it is unarguable that present day nitrate-levels (1-9 mg L^{-1} in larger European rivers) are severely above those concentrations where most aquatic life has evolved. During the past decades, deviations in wildlife reproductive hormone levels and sex ratios have been reported in organisms ranging from alligators, newts, fish and frogs to small crustaceans. Despite much research effort, no single major cause of the observed changes has been found. This poster presents a compilation of the growing experimental evidence for environmental endocrine disruption by inorganic nitrate. It furthermore describes three hypotheses regarding the mechanisms by which nitrate may cause endocrine disruption: 1) Nitrate affects homeostasis by interfering with chloride and/or iodide ion transport, 2) Nitrate is converted to nitric oxide, which affects homeostasis by altered transcription of relevant genes and/or altered activity of relevant enzymes, and 3) Nitrate acts synergistic in combination with other environmental pollutants. It is likely that different species have very different sensitivities, as they have evolved in environments of different nutrient status and have inherently different hormonal systems. Future research must therefore include different ecologically relevant organisms and provide information on threshold concentrations, developmental "sensitivity windows" as well as addressing the hypothesized mechanisms.

MO008

Fate of antibiotics in pulsed corona discharge oxidation

M.V. Kråkström, Abo Akademi University / Organic Chemistry; A. Sokolov, M. Louhi-Kultanen, Lappeenranta University of Technology / Chemical Technology; L. Kronberg, Abo Akademi University

Antibiotics in the environment are of concern due to the development of antibiotic resistant bacteria. Conventional wastewater treatment plants are not designed to remove micropollutants such as antibiotics. Thus, a significant amount of these compounds are released into the aquatic environment. The gas-phase pulsed corona discharge process (PCD) is an effective, environmentally friendly method for removing recalcitrant organic compounds in waste water. In PCD organic compounds are transformed through reactions with hydroxyl radicals and ozone. The objective of this work is to optimize PCD oxidation for the antibiotics sulfamethizole, doxyxycline and amoxicillin. Quantitative analyses of the antibiotics and their oxidation products will be performed and the main oxidation products will be fully characterized. A preliminary structural characterization of oxidation products was performed on the basis of molecular weight determination by a time of flight mass spectrometer, and fragmentation pattern recorded by an ion trap mass spectrometer. Final structural determination will be performed by NMR studies (^{1}H and ^{13}C NMR) on isolates obtained through semi-preparative LC fractionation of reaction mixtures. Subsequently, an exact quantification of the main products will be performed with a triple quadrupole mass spectrometer using the isolated compounds as authentic standards. The preliminary results show that amoxicillin forms nine transformation products of which five have been tentatively identified. Sulfamethizole forms many minor products of which the structures of five products have been preliminarily elucidated. Doxycycline forms two major products, both of which have been tentatively identified. The most common transformations are those where one or hydroxyl groups are added to the parent compound and ring opening of the β-lactam ring in amoxicillin.

MO009

WASTEFFECT: Life cycle management of emerging contaminants in waste with a focus on flame retardants

H. Arp, N. Morin, NGI / Environmental Engineering; G. Okkenhaug, NGI; . AlmÃs, NMBU; S. Hale, M. Sparrevik, NGI; P. Andersson, Department of Chemistry UmeŃ University; K. Breivik, Norwegian Inst. for Air Research; F. Wania, University of Toronto Scarborough / Physical and Environmental Sciences; G.D. Breedveld, NGI / Department of Environmental Engineering

Waste treatment has become a dynamic sector. In many countries, waste-handling infrastructure is changing from doing less landfilling and more incineration or recycling, in order to maximize energy and material re-capture. In addition to materials and energy, waste also contains a large variety of contaminants of emerging contaminants (CEC), and yet how landfilling, incineration, and recycling can effect environmental emissions and exposures of such CECs remains largely overlooked. Two such emerging contaminants found in increasing levels in waste include brominated flame retardants (BFRs) and antimony. The Norwegian research project WASTEFFECT focused on how these CECs and other contaminants behave in different waste streams, like landfilling, incineration and recycling. WASTEFFECT researchers sampled air and water emissions around several waste-handling facilities, and ultimately established a Norwegian waste emission inventory of BFRs and antimony in electronic-waste, car waste, plastics, glass and combustible waste. Collectively these data show the contribution of the waste sector to emissions of CEC in the environment, as well as how effectively the eliminate CECs from the environment. The main output of this research will help guide the waste management sector on which of the treatment methods provide the lowest risk in regards to emerging chemicals, and which processes could be optimized. These results are also of relevance to a better understanding of potential CEC risks to areas around and down-stream of waste handling facilities.

MO010

The occurrence of antibiotics in wastewaters, recipient waters and sediments

E.M. Kortesmäki, Abo Akademi University / Department of Natural Sciences; A. Meierjohann, Abo Akademi University / Laboratory of Organic chemistry; L. Kronberg, Abo Akademi University

In recent years, the occurrence of antibiotics in the environment has generated a major concern among the public and decision makers because of their possible impact on the aquatic ecosystem and possible development of antibiotic resistant bacteria. Antibiotics have been shown to enter the environment through target organisms' excretion mainly *via* discharges from wastewater treatment plants (WWTPs), through the use of animal manure in agricultural fields and through direct discharge from aquaculture. It has been shown that even the relatively low concentrations of antibiotics found in WWTPs and in the environment can give rise to the selection of antibiotic resistant bacteria. However, more data on the occurrence and fate of antibiotics is needed before an actual risk assessment of their impact can be done. The overall objective of the work was to determine the occurrence and fate of 17 most used antibiotics in Finland in WWTPs, in recipient waters and sediments. Twenty-four hour composite samples were collected from the influent and effluent waters in the WWTPs in three consecutive days. WWTPs were chosen to represent different profiles by their working efficiency, characteristics of their incoming wastewater and size. Additionally, surface and bottom water samples as well as sediment samples were taken from the discharge points of the WWTPs and from the Archipelago Sea (which is rich in fish farming industry). The analytical method developed for the analysis of 17 antibiotics and 3 metabolites (tetracyclines, β-lactams, macrolides, quinolones and sulfonamides) in this study combines on-line solid-phase extraction (SPE) extraction and LC-MS/MS identification and quantification (an existing pre-treatment technique of SPE with liquid chromatography mass spectrometry triple quadrupole through on-line connection). An anti-epileptic drug carbamazepine was used as a tracer for wastewater contamination. Isotopically labeled isomers of the analyzed compounds were used for quantification. Obtained results show that nine antibiotics could be detected frequently at concentrations ranging from 500 ng l^{-1} in the influent to low ng l^{-1} in the effluent waters. Clarithromycin, erythromycin and trimethoprim were found close to the discharge point (at the nearest sampling location from the discharge point) at concentrations ranging from 5 to 52 ng l^{-1}.

Preliminary results also show that some antibiotics can be detected in sediment samples taken from the Archipelago Sea.

MO011

Application of Multimedia Urban Model to estimate the environmental fate of PAHs in Tarragona County, Spain

N. Domínguez, URV/IISPV; M. Marques, Rovira i Virgili University / Chemical Engineering; M.L. Diamond, University of Toronto / Department of Earth Sciences; J. Sierra, Universitat Rovira i Virgili / Soil Science Unit; M. Schuhmacher, Rovira i Virgili University / Chemical Engineering; J.L. Domingo, Universitat Rovira i Virgili / Laboratory of Toxicology and Environmental Health; M. Nadal, University Rovira i Virgili / Laboratory of Toxicology and Environmental Health

Concern regarding polycyclic aromatic hydrocarbons (PAHs) continues because of their ubiquity in the environment and relatively high toxicity. PAHs are emitted from incomplete or low temperature combustion processes and their environmental burdens are a function of proximity to emission sources. Numerous studies have demonstrated elevated concentrations of PAHs in urban areas. For this reason, predicting the environmental fate and transport of PAHs is an essential step in the process of assessing the impacts of these contaminants in the urban and surrounding environment. The goal of this research was to estimate the fate and dynamics of PAH in Tarragona County, Spain, that is home to the most important chemical/petrochemical industrial complex in Southern Europe. To achieve this goal we used the Multimedia Urban Model (MUM-Fate) of Diamond et al. (2001, Chemosphere 44, 1655-1667). This model is based on the Level III fugacity model of D. Mackay (Multimedia Environmental Models: The Fugacity Approach, Lewis Publishers, Boca Raton, FL, 1991) and consists of seven bulk media compartments: lower and upper air, surface water, sediment, soil, vegetation and an organic film that coats impervious surfaces. This model is characterized by considering impervious surfaces, which are a unique feature of urban environments. Here, MUM-Fate was parameterized according to conditions in Tarragona County and then run with an illustrative emission rate of 1 mol/h for six PAHs, Naphthalene, Anthracene, Phenantrene, Fluoranthene, Pyrene and Benzo(*a*)pyrene. Results from the MUM-Fate model showed that the film compartment achieves highest concentrations of PAHs studied, followed by soil, sediment and vegetation compartments in descending order. In contrast, soil and sediment were the greatest sinks for PAHs in Tarragona County, because they receive high inputs from air, water and vegetation relative to low losses. By far the greatest loss of PAH was due to advection from air, followed by photodegradative reactive losses from air. Although the general pattern was similar to that seen in Toronto, Canada, more PAH were lost via air advection and photodegradation whereas less PAH accumulated in vegetation, water, soil and sediment because of lower precipitation in Tarragona with its semi-arid climate. These results provide a first approximation of the fate of PAH in Tarragona County, an area highly impacted by the petrochemical industry.

MO012

Assessing the potential effects of reclaimed waters on aquatic organisms using a test battery with standardised and novel bioassays.

M. Pablos, INIA - National Institute for Agricultural and Food Research and Technology / Environment; P. Garcia, INIA National Institute for Agricultural and Food Research and Technology / Department of Environment; M. Gonzalez-Doncel, National Institute for Agricultural and Food Research and Technology / of the Environment; E.M. Beltrán, INIA - National Institute for Agricultural and Food Research and Technology / Environmental; C. Fernández, National Institute for Agricultural and Food Research and Technology / Department of Environment Laboratory for Ecotoxicology; M. Aquilino, UNED; J. Martinez-Guitarte, UNED / Fisica Matematica y de Fluidos; P. Sanchez-Arguello, INIA - National Institute for Agricultural and Food Research and Technology / Environment

Climatic change is causing more persistent drought periods in the Mediterranean basin as they reduce availability of water sources and increase undesirable impacts on aquatic ecosystems. The use of reclaimed waters for irrigation and aquaculture purposes is generally considered a reliable alternative for sustainable water management, particularly in those regions with high water demand vs. water availability. Recently, a large number of organic compounds, which are generally categorised as emerging contaminants, has been detected in wastewater effluent. To date, no quality criteria have been proposed for this group of compounds, so they cannot be controlled according to existing Spanish Legislation on reclaimed waters use (RD 1620/2007). Reclaimed water samples, supplied by four Spanish WWTPs that collect effluent of different origins (municipal only or municipal and industrial), which undergo distinct tertiary treatments, were used herein. Chemical characterisation was performed and 44 emerging pollutants, classified as pharmaceuticals, parabens, UV filters and endocrine disruptors, were analysed. A complete test battery was conducted to detect sublethal or chronic effects, which covered all taxonomic groups representative of the aquatic compartment. This bioassays battery included a modified standardised growth inhibition test on algae (OECD, 201), the standardised reproduction test on *Daphnia magna* (OECD, 211), a *Daphnia magna* feeding assay, an embryotoxicity and a reproduction test on *Physa acuta*, an embryo life cycle test on *O. latipes,* and a modified embryotoxicity test on *X. laevis* (ASTM, 1998). Reclaimed waters, dilutions of these waters (10%, 50%) and reclaimed waters spiked with high concentrations of a mixture of methylparaben, PFOs and fluoxetine were tested in this test battery. The results showed differences in the toxicity of samples, with good correlation between assays in some cases. The wide variety of studied endpoints enabled the complete biological characterisation of these samples, which confirmed the utility of the test battery to assess the potential effects of complex mixtures as reclaimed waters. This work was possible thanks to Spanish Ministry of Economy and Competiveness projects CTM2013-44986-R and CTM2014-52388-R.

MO013

Understanding the fate of active pharmaceutical compounds in surface waters receiving poorly or untreated sewage effluent and the development of appropriate environmental risk assessment approaches

S. Bagnis, Plymouth University; S. Comber, Plymouth University / Environmental Science; M. Fitzsimons, Plymouth University; J. Snape, AstraZeneca UK Ltd. / AstraZeneca Global Environment; A. Tappin, Plymouth University

Active pharmaceutical compounds (API's) have been classified as emerging contaminants, and their introduction in the environment might pose risks to ecosystems. The main source of pharmaceuticals in the environment is human use and excretion or the improper of unused mediation to the sewerage system. In wastewater treatment works the lack of efficient removal of some pharmaceuticals, combined with pseudo-persistence, results in their presence in surface waters. As patient access to medicines increases in developing countries the environmental concentration of pharmaceuticals has the potential to be higher than in developed countries if the level of wastewater and drinking water treatment does not also increase. Untreated wastewater enters the environment via discharge into surface waters resulting in a downstream area characterized by high pollution, named "impact zone". Characterization of the environmental risk posed by pharmaceuticals in such an area is challenging since the formal protocol for environmental risk assessment was developed for environmental conditions largely different from the ones encountered in the impact zone; High levels of BOD, ammonia, and other potential toxicants exist in combination with low concentrations of dissolved oxygen, meaning that there is an absence of traditional species used for toxicological endpoints. Therefore, the calculation of predicted environmental concentrations (PEC) in such conditions is not relevant. The aim of the research is to obtain a comprehensive overview of the gaps regarding the fate of pharmaceuticals in aquatic environment initially starting with an extensive literature review of available data for (1) occurrence, (2) degradation rates, (3) partitioning to dissolved organic matter, colloids and suspended solid matter, and (4) relevant endpoints. This will inform experimental research aimed at gaining data about partitioning and degradation of selected pharmaceuticals in the impact zone at varying dilutions, and determination of proper endpoints. The information obtained will be used to develop an environmental risk assessment approach for impact zones, as only with more accurate exposure concentrations and impact data can the risks to the aquatic environment of APIs be quantified.

MO014

The Chemical Investigations Programme Phase 2: an assessment of the presence of pharmaceuticals in wastewater treatment works influent and effluent

V. Jones, M.J. Gardner, Atkins Ltd.; D. Leverett, WCA-Environment Ltd

There is increasing interest in the presence of Active Pharmaceutical Ingredients (APIs) in the aquatic environment due to their potential environmental impact. The Water Framework Directive (WFD) "Watch List" currently includes three APIs (E2, EE2 and diclofenac) with the potential for inclusion of further such compounds in future revisions of the Directive. Wastewater treatment works (WwTWs) effluent is the primary source of APIs into the environment. The Chemical Investigations Programme (CIP) Phase 1 took place between 2007 and 2013 and examined the presence of a range of trace substances in WwTW influent and effluent, including selected APIs, across mainland UK. The results of this large-scale study indicated the need for further study to examine issues at a more localised scale and consider solutions. The CIP Phase 2 started in 2015 and includes monitoring at 600 WwTWs over a period of 5 years across England and Wales. The study encompasses monitoring of 23 key APIs, such as propranolol, carbamazepine, ibuprofen, tamoxifen and four antibiotics. This poster will present an outline analysis from the first "tranche" of results from the CIP2 study focusing on APIs in influent and effluent. Comparisons with Predicted No Effect Concentrations (PNECs) which have been developed for each API will also be presented, taking into account the dilution of each WwTWs effluent, as well an assessment of removal during the treatment process at different sites.

MO015

Presence of virulence genes in Enterococcus spp. isolated from South African environmental water systems

L.G. Molale, North West University (Potchefstroom Campus) / Microbiology; C.C. Bezuidenhout, North - West University / Unit for Environmental Sciences and Management

Enterococcus spp. from environmental sources harbouring virulence factors may not always express functional gene products. However, their presence may be

indicative of potential pathogenicity and could also contribute to the spread of these genes in the environment. The aim of this study was to determine the relationship between the presence of selected virulence genetic determinants and the expression of these factors from environmental water from the North West province of South Africa. A total of 93 enterococcus isolates, consisting of six species, were screened for the presence of 5 virulence determinants (*asa1, cylA, esp, gelE* and *hyl*) using PCR (polymerase chain reaction). Furthermore, the expression of *cylA, hyl* and *gelE* were determined by phenotypic assessments illustrating β-haemolysin, hyaluronidase and gelatianse activity. Seventy percent of the screened isolates harboured at least 1 virulence gene whilst 15% harboured 2 or more. The most frequently detected virulence genes were *cylA* and *gelE*. However, *asa1* and *hylA* were also detected. Enterococcal surface protein (*esp*) was the only virulence determinant absent in all screened *Enterococcus* spp. The presence of virulence genes was correlated with their extracellular enzyme production. Only 40%, 22% and 22% of the *cylA, gelE* and *hyl* gene carrying isolates produced β-haemolysin, gelatinase and hyaluronidase, respectively. The results of this study show that a large percentage of these environmental enterococci (including E. *faecalis, E. faecium, E. mundtii, E. casseliflavus, E. gallinarum* and *E. hirae*) possess virulence factors and that these could be expressed *in vitro*. This could have implications for individuals using this water directly for recreational and other purposes. Therefore measures to minimize their presence in such water sources are vital. **Keywords:** *Enterococcus* spp.; environmental water systems; virulence genes; extracellular enzyme production

MO016

OCCURRENCE OF 16 ILLICIT DRUGS IN CEYHAN RIVER, TURKEY

E. Guzel, F. Cevik, University of Cukurova / Department of Fisheries Basic Sciences; N. Daglioglu, University of Cukurova / Department of Forensic Medicine

Illicit drug concentrations in surface waters which under the influence of waste water treatment plants can be an indirect tool to estimate the community level of consumption of illicit drugs. These drugs enter the surface waters unaltered or slightly transformed via waste water effluents by human excretion after illegal consumption, by intentional extermination from undercover drug laboratories or by accidental. The illicit drugs and their metabolites are very recalcitrant to elimination at conventional waste water treatment plants. In the current study, which is one of the first studies in Turkey, presence and seasonal variability of 16 illicit drugs and metabolites in Ceyhan River, which places in Southern Turkey was investigated. Water samples were collected from 9 stations at seasonal intervals for one year to characterize the seasonal variability of drugs. One of these stations was near the Osmaniye waste water treatment plant. As a part of this study, a sensitive and selective liquid chromatography-tandem mass spectrometry (LC-MS/MS) screening method targeting 16 illicit drugs has been developed and employed to investigate the occurrence of these drugs in water samples. Solid phase extraction techniques were used for all samples. 16 different illicit drugs and metabolites (6-MAM, cocaine, codeine, fentanyl, hydrocodone, hydromorphone, JWH-018, JWH-073, ketamine, MDA, MDMA, amphetamine, methamphetamine, methylecgonine, morphine, tramadol) were examined with LC-MS/MS. Fourteen of these drugs couldn't be found in the river water samples. Cocaine and tramadol were detected in 77.8% of the river water samples. The concentrations found in the water samples in the low ng/L range. Median cocaine concentration was 0.404 ng/L, and tramadol concentration was 0.420 ng/L. Highest illicit drug concentrations were detected in the station close to the wastewater treatment plant and summer season. Environmental concentrations of these illicit drugs are low, but they may be toxic to the aquatic organisms. Risks to the environment and human health are under consideration and further studies about the occurrence and toxicology should be done.

MO017

Mixture toxicity effect of bisphenol AF and sulfamethoxazole on thyroid endocrine system in zebrafish

K. Ji, B. Kwon, S. Jang, Yongin University; B. Kim, Department of Environmental Health

Bisphenol AF (BPAF) is widely used in the production of polycarbonate copolymers as an alternative of bisphenol A. Given the complex nature of mixtures of environmental pollutants in aquatic systems, the present study aimed to evaluate potential for thyroid endocrine disruption in fish co-exposed to BPAF and sulfamethoxazole (SMX). Adult male zebrafish were exposed to control, BPAF (50 μg/L), SMX (50 μg/L), and a binary mixture of BPAF and SMX for 21 days, and the effects on growth and tissue somatic index were examined. Concentrations of thyroxin (T4) and expression of mRNAs for 10 functionally relevant genes of the hypothalamic-pituitary-thyroid axis were also measured. Microarray analysis was performed to identify altered genetic targets by pooling total RNAs from three individual fish in each treatment group. Significant increase of thyroid somatic index was observed in fish exposed to a mixture of BPAF and SMX. Expressions of *trh*, *tshr*, and *tshβ* genes in thyroid were significantly increased when fish were co-exposed to BPAF and SMX. With a combined exposure to BPAF and SMX, the extent of increase in gene expressions and T4 hormone production were more pronounced than those of BPAF only exposure group. Moderate correlation between microarray and gene expression values was observed. The present study indicates that combined exposure to SMX could significantly increase an endocrine disrupting effect of BPAF.

MO018

Toxic and genotoxic potency of rainwater samples from Greece on bacteria and human cells

M. Antonopoulou, A. Lavranou, University of Patras / Department of Environmental and Natural resources Management; I. EFTHIMIOU, University of Patras / Department of Environmental and Natural Resources; F. Konstantinou, University of Patras / Department of Environmental and Natural resources Management; I. Konstantinou, University of Ioannina / Chemistry; D. Vlastos, University of Patras / Department of Environmental and Natural resources Management

Rainwater is considered as the main route of pollution from the atmosphere to the aquatic ecosystems. Despite the significant effect of rainwater quality on the different levels of trophic chain, a relatively small number of studies has been conducted regarding the impact of rainwater to living organisms and microorganisms. The main focus of the present work is to provide novel knowledge in relation to the potential adverse effects of rainwater on aquatic ecosystem and human health. In this context, the toxic and genotoxic effects of various rain water samples collected from three urban cities of Western Greece were estimated. Acute toxicity of the rainwater samples was evaluated by monitoring the inhibition of the luminescence emitted by the marine bacterium *Vibrio fischeri,* using a Microtox system (Azur Environmental). The cytotoxic and genotoxic potential activity of rainwater samples was assessed employing the cytokinesis block micronucleus (CBMN) assay. The physicochemical composition of the samples was also determined. The pH values of rain samples ranged between 5.8 and 7.2, indicating a reduction of the pH index during the summer months. In contrast, conductivity increased, in the same sampling periods. Chemical analysis revealed that SO_4^{2-} followed by Cl^- were the dominant anions in the majority of the samples. The increased concentration of chloride ions in the rainwater samples from cities situated in coastal zones is probably correlated with the transport of seawater aerosol. Concerning the % inhibition of luminescence of the bacterium *Vibrio fischeri,* the highest percent of inhibition was observed to the samples collected during the summer months. The results of the CBMN assay showed an induction of genotoxicity in the rainwater samples on the month of December in all urban areas, as well as a cytotoxic activity in the majority of the samples with a most pronounced increase during the summer months. Correlation between obtained toxicity data and chemical composition of the samples proved significant contribution of ions that originate from anthropogenic sources (nitrogen ion species) in the observed toxic effects.

MO019

Occurrence of seven bisphenol analogues in paper products from Korea: Implications for regulation and human exposure

J. Lim; S. Lee, Hanyang University; H. Moon, Hanyang University / Marine Sciences and Convergent Technology

Bisphenol A (BPA) has been produced for the past decades with wide variety of commercial products, such as polycarbonate plastics and epoxy resins. Humans are mainly exposed to BPA through diet and dermal absorption from the use of paper products is also considered as a major exposure route to BPA for humans. Recently, BPA has been used in paper products including thermal receipt paper, currency bills, and business cards. As the concerns for toxic effects of BPA grows, BPA is gradually being replaced to related compounds such as bisphenol S (BPS) and bisphenol F (BPF). However, limited information is available concerning the occurrence of bisphenol analogues (BPs) in the paper products. In this study, the concentrations of seven BPs (BPA, BPS, BPF, bisphenol AF (BPAF), bisphenol AP (BPAP), bisphenol Z (BPZ), bisphenol P (BPP)) were measured in six types of paper products (n = 153), including thermal receipts, paper currencies, business cards, airplane boarding passes, cafe coupons, and newspapers collected from Korea. In all paper products, BPA showed the highest detection rate (88%), followed by BPZ (47%) and BPS (16%). Among paper products, thermal receipt contained the highest levels (mean: 2.19 mg/g) of BPA, compared with other paper products (mean: 1.5 μg/g). In particular, seventeen thermal receipts (14% of total) showed the higher levels of BPS (mean: 1.04 mg/g) than BPA (mean: 0.017 mg/g), implying the evidences that BPA is replacing into BPS. These 17 receipts have 'BPA-free' labeled in common on the back of receipts. Our findings indicate that BPA is still used as a predominant analogue in thermal receipt papers, but BPA is replaced into BPS. The daily intake (EDI) of BPA associated with dermal absorption of paper products was estimated to be 2.91 ng/day for general population and 8905 ng/day for occupationally exposed populations in Korea. Among paper products, thermal receipt papers contributed to most (>70%) of the BPA exposures for dermal consumption. Considering high occupational exposure groups, survey and risk assessment for the exposure of BPs in thermal receipt would be necessary.

MO020

QuECHERS as perspective extraction technique for isolation of steroid

estrogens from sediments in environmentally relevant concentrations

J. Sadílek, RECETOX, Faculty of Science, Masaryk University / Research centre for toxic compounds in the environment; P. Spalovska, Masaryk University / Research centre for toxic compounds in the environment; M. Vavrova, University of Technology Brno / Institute of Chemistry and Technology of Environmental Protection; B. Marsalek, Institute of Botany ASCR / Department of experimental phycology and ecotoxicology; Z. Simek, Masaryk University / Research centre for toxic compounds in the environment

The presence of endocrine disrupting compounds including steroid estrogens in water environment is worldwide problem. These compounds are released from different sources such as wastewaters from household through ineffective wastewater treatment plant also as result of runoff from agricultural areas after animal manure applications. Steroid estrogens cause a negative effect on growth, development and reproduction of aquatic organisms at very low concentrations. Due to higher octanol-water partition coefficient they tend to sorption and accumulation to solid matrices such as sediments. For a study of estrogens behavior in water-sediment system the effective extraction technique is needed. For this reason the four extraction technique: Soxhlet warm extraction (SWE), Accelerated solvent extraction (ASE), Microwave assisted extraction (MAE) and Quick Easy Cheap Effective Rugged Safe (QuCHERS) were compared using different extraction conditions. Estron (E1), 17α – estradiol (αE2), 17β- estradiol (βE2), estriol (E3), 17α-ethinilestradiol (EE2) and 17α-ethinilestradiol 2,4,16,16-d4 (EE2d4) were extracted from sediment samples at very low initial spike concentrations (1ng/g). Wider range of extraction recoveries (40-120 %) was considered as acceptable in those cases. Simple, fast and inexpensive original QuECHERS with PSA clean up provided the best extraction recoveries for all tested estrogens (53-84 %). Also MAE achieved the satisfactory extraction efficiency using DCM:acetone 3:1 as extraction solvent (50-70 %) but only for less polar estrogens. For estriol the more polar extraction solvents (acetone or methanol) must be used. More time consuming extraction technique ASE provided lower extraction recovery or worse repeatability in almost all solvent-temperature combinations in comparison with previous extractions. The worst results were obtained by most time consuming technique SWE that is totally unsuitable for this purpose. This comparison also showed that the correct choice of internal standard for calculation of final estrogens concentrations is very important due to great complexity of sediment samples. Deuterated 17β-estradiol was firstly used in SWE and ASE as internal standard for all tested estrogens but these compounds cause an overestimation of E3. For this reason deuterated 16α-hydroxy-17β-estradiol was selected as preferable internal standard for E3. *Acknowledgment: Reserch was funded by GACR GA13-20357S*

MO021

Transformation products of quetiapine formed by UV treatment and biodegradation

M. Herrmann; O. Olsson, Leuphana University of Lüneburg / Institute for Sustainable and Environmental Chemistry; K. Kümmerer, Leuphana University of Lüneburg / Sustainable Chemistry and Material Resources

Quetiapine (QUT) arouse much attention in recent years for the treatment of schizophrenia and bipolar disorders. As QUT is consumed in high amounts and is not efficiently removed by sewage treatment plants (STPs), it has been frequently detected in secondary effluent. UV treatment could be a possible advanced treatment option to eliminate QUT. Moreover, the release of QUT to surface water is very likely, and therefore, the fate regarding biodegradability of QUT needs to be assessed. UV treatment of QUT in ultrapure water at different concentrations (86.9, 17.4 and 4.3 mg/L) was conducted. The primary elimination and the mineralization was monitored for 128 min by means of HPLC-UV and NPOC, respectively. QUT and the photolytic mixture after 128 min of UV treatment were submitted to biodegradation tests using different bacterial density and test compound concentration, namely the Closed Bottle Test (CBT; OECD 301D) and the Manometric Respiratory Test (MRT; OECD 301F). Structures of photo- and biotransformation products (PTPs and BTPs, respectively) were elucidated by high-resolution mass spectrometry. At high initial concentration of 86.9 mg/L, QUT was not completely eliminated after 128 min of UV treatment. Primary elimination followed zero order kinetics ($t_{1/2}$ = 100 min). NPOC recovery was 97% indicating the formation of PTPs. The elimination half-life increased at initial concentration of 17.4 and 4.3 mg/L fitting a first order model ($t_{1/2}$ = 24 and 5 min, respectively), while NPOC recovery was 95 and 30%, respectively. In the CBT and the MRT, QUT was not readily biodegradable according to OECD test criteria (16.6 ± 1.5% and -1.9 ± 3.2%, respectively), while QUT was primary eliminated to some degree (20.2 ± 3.9% and 88.8 ± 10.9%, respectively) indicating the formation of BTPs. The extent of biodegradation regarding biochemical oxygen demand (BOD) of the photolytic mixture was not increasing compared to QUT. Several PTPs and BTPs have been identified and structurally elucidated. PTP 400 (sulfoxide derivative) and BTP 398 (carboxylic acid derivative) are also formed to a high extent as human metabolites. UV treatment of secondary effluent contaminated with QUT could result in formation of PTPs. These PTPs cannot be generally seen as better biodegradable. Therefore, UV treatment should be considered critically as a possible treatment option in this respect. BTPs of QUT should be further characterized regarding their potential toxic effects in the environment.

MO022

Bisphenol A alternatives cause reproductive endocrine disruption in zebrafish (Danio rerio)

K. Ji, B. Kwon, S. Jang, Yongin University; B. Kim, Department of Environmental Health; j. Lee, Yongin University

Although the toxic effects of waterborne bisphenol A (BPA) exposure were frequently studied in aquatic organisms, limited information is available on the toxicity of BPA alternatives, such as bisphenol analogues or Tritan^{TM} copolyesters. In the present study, reproductive endocrine disruption of bisphenol AF (BPAF), bisphenol S (BPS), and one of the main component of Tritan^{TM} copolyesters (1,4-cyclohexanedimethanol (CHDM)) in zebrafish were investigated. Adult zebrafish pairs were exposed to environmentally relevant concentrations of BPAF (0.5~50 μg/L), BPS (0.5~50 μg/L), and CHDM (0.1~10 μg/L) for 21 d, and the effects on reproduction, sex steroid hormones, and transcription of the genes belonging to the hypothalamic-pituitary-gonad axis were examined. The adverse effects on performances of F1 generation were further examined. The average number of eggs spawned was significantly less upon the exposure to ≥0.5 μg/L BPAF and BPS, while no significant changes were observed in fish exposed to CHDM. Exposure to two bisphenol analogues resulted in estrogenicity in male fish, showing significant increase in plasma 17β-estradiol (E2) concentration. The increase of E2 is well supported by significant up-regulation of aromatase (cyp19) gene, which catalyzes the final step in conversion of androgen to estrogen. Parental exposure to BPAF and BPS resulted in delayed hatching and increased malformation rates. Given the importance of endocrine function, further investigations on underlying mechanisms of sex-dependent responses in zebrafish are needed. Acknowledgement – This study was supported by National Research Foundation of Korea (Project no. NRF-2015R1D1A1A01056628).

MO023

Characterization of samples by endocrine activity profiles using the planar yeast estrogen screen (pYES)

S. Buchinger, Federal Institute of Hydrology / Department G Biochemistry Ecotoxicology; D. Spira, A. Bell, K. Broeder, M. Schluesener, German Federal Institute of Hydrology; T. Ternes, German Federal Institute of Hydrology BfG; G. Reifferscheid, Federal Institute of Hydrology / Department Biochemistry and Ecotoxicology

Recently, a protocol for the direct combination of thin layer chromatography and the yeast estrogen screen (pYES) was developed as a screening tool for effect directed analysis (EDA). The advantages of this approach lie in its rapidness compared to an EDA-approach with e.g. HPLC and a subsequent analysis of fractions for biological activity and in its robustness. The method allows for the analysis of effects in demanding matrices. The pYES supports compound identification by the possibility to quickly falsify alternative compounds and by the direct accessibility of the compounds on the TLC-plate to a subsequent analysis by mass spectrometry. Qualitative and quantitative results about specific effects in mixtures can be obtained within one working day. Activity profiles of samples can be generated easily which allow a comparative assessment of alternative processes for e.g. wastewater treatment without a detailed chemical analysis. Furthermore, sources of environmental contamination can be identified and characterized based on biological effects rather than compounds, i.e. a source-identification is independent from the knowledge about defined chemical compounds. Due to the high sensitivity of the method it is possible to detect less than 30 pg/l 17a-ethinylestradiol and 17b-estradiol after a 1000-fold concentration. The pYES might thus serve as a screening tool for the characterization of these compounds in surface waters according to the watch list of the EU water framework directive. Taken together, the pYES-approach seems to have a high potential to be used as a fast and robust screening tool for various applications in effect directed analysis. The approach is complementary to the more common combination of HPLC with a subsequent bioassay.

Evaluation of the acute toxicity and genotoxicity of pyrolytic tire chars

M. Dormousoglou, Department of Environmental and Natural Resources ManagementUNIVERSITY OF PATRAS; M. Antonopoulou, F. Konstantinou, University of Patras / Department of Environmental and Natural resources Management; I. Konstantinou, University of Ioannina / Chemistry; D. Vlastos, University of Patras / Department of Environmental and Natural resources Management

The disposal of waste tires constitutes a major problem with environmental and financial impact worldwide. The last decades, pyrolysishas received considerable attention for the management of waste tire disposal resulting simultaneously in the recovery of valuable productssuch as oil and gas fractions, as well as pyrolytic char. Pyrolytic char from tire-rubber (PyrolyticTyre Char, PTC) is a carbon material similar to carbon black (CB), extensively used as adsorbent or support. As adsorbent, PTC has exhibited promising results for the removal of organic and inorganic pollutants from aqueous media. In recognition of its potential application in aquatic remediation, in the present study toxicity, genetoxicity and cytotoxicity potential of PTC (untreated and acid (HNO_3-treated) was investigated

for the first time. The acute toxicity of PTCs was evaluated using the marine bacteria *Vibrio fischeri*, which emit bioluminescence as a byproduct of cell respiration and normal metabolic process, by a Microtox Model 500 Analyzer (AzurEnviromental). In each experiment, the % inhibition of the luminescence and the EC_{50} values (mean sample concentration that causes a 50% reduction in bacteria bioluminescence) were recorded after 5, 15 and 30 min of incubation. The genotoxic and cytotoxic activity of the untreated and acid-treated PTC was studied applying the cytokinesis block micronucleus (CBMN) assay in human lymphocytes *in vitro*. Both the untreated and acid-treated PTC were studied at three different doses i.e. 2.5, 5 and 10 mg L^{-1}.The EC_{50} values for the untreated and acid-treated PTC after 30 min of exposure were determined as 486 and 163 mg L^{-1}, respectively. Both the untreated and acid-treated PTC were found to be genotoxic at all the tested concentrations in the CBMN assay. In the case of acid-treated PTC a slight decrease in MN frequency was observed. Regarding the cytotoxicity, both PTCs induced cytotoxic activity in all the tested concentrations.

MO025

A comparison of micropollutant removal in different biological wastewater treatment plants

O. Komolafe, P. Meynet, Newcastle University / Civil and Environmental Engineering; J. Dolfing, Newcastle University / School of Civil Engineering and Geosciences; W. Mrozik, Newcastle University / School of Civil Engieenering Geoscience; R. Davenport, Newcastle University / School of Civil Engineering and Geosciences

Concerns over the effects of chemicals in the aqueous environment has seen the introduction of more stringent water quality regulations and tertiary treatment using advanced oxidation processes such as ozonation. These interventions make existing wastewater treatment more energy-intensive; aeration in activated sludge alone accounts for up to 1.5% of UK electricity use. The transition to carbon-neutral wastewater treatment will require the adoption of low-energy biological treatment systems that operate with little or no active aeration, such as those extensively used in Latin America (upflow anaerobic sludge blanket reactors; UASBs and waste stabilisation ponds; WSPs). Little is known about the true biological limits of micropollutant removal especially in low-energy systems. In this study we wanted to investigate a range of structurally diverse micropollutants with varying degrees of halogenation towards that goal. We started by validating analytical methods for the quantification of triclosan, PAHs and PBDEs using SPE-GC-MS and SPE-LC-MS and using them to assess triclosan and PAH removal in two UK WWTPs. Recoveries of the compounds in wastewater was between 70 – 130% with a relative standard deviation of ≤ 20. Method detection limit of triclosan in effluents was 5 ng/L, while low molecular weight PAHs was 0.4 – 1.2 ng/L and high molecular weight PAHs was between 4 and 12 ng/L. The concentration of triclosan in effluents from both WWTPs was above the Predicted No-Effect Concentration (PNEC) of triclosan in freshwater (i.e. 100 ng/L). PAHs concentration in the effluent exceeded their EQS standards and about 90% of total PAH concentration partitioned in the suspended particulate matter. We are currently determining first order biodegradation rates for the chemicals under aerobic and anaerobic conditions, and will assess their fate and removal in real UASBs and WSPs from Brazil compared to conventional systems.

MO026

Extended application of a human pharmaceuticals emission model to the assessment of metabolites.

E. Han, D. Lee, Seoul National University / Environmental Planning Institute Graduate School of Environmental Studies

Accurate prediction of emission is critical to assessing and managing exposure to pharmaceuticals in freshwater, particularly because extensive monitoring data are often lacking. In our previous work (1), an emission prediction model was presented with the uncertainties associated with its prediction of human pharmaceuticals discharged into the typical Korean river environment. The model covers the stages of pharmaceutical life cycle posterior to domestic production and import, including distribution, consumption, disposal, and waste treatment. In the present work, the emission model was combined with SimpleBox and SimpleTreat into a single spreadsheet-type model for calculating the predicted environmental concentrations of the human pharmaceuticals and their metabolites. For metabolites, the stages of life cycle were appropriately adjusted from after intake of the parent pharmaceutical through to the discharge. This model was then used to determine the whole hazard quotients by taking into account not only human pharmaceuticals but also their metabolites in surface water of Korea. From all the human pharmaceuticals sold above 1,000 kg in 2011 in Korea, 6 pharmaceuticals (acetaminophen, allopurinol, cefepime, furosemide, ofloxacin, and theophylline) were selected of which metabolite information (species, formation rate, and excretion rate) is available from public database. As predicted no effect concentration data of the selected pharmaceuticals and their metabolites are scarce, ECOSAR was used for toxicity estimation. The metabolites of acetaminophen and theophylline were found to have the hazard quotients that are of comparable magnitude with those of their parent pharmaceuticals. As the finding strongly suggests a need to assess the environmental risk posed by metabolites, the model developed in the present work can be used as a quantitative tool to efficiently screen the human pharmaceuticals concerning the potential risk from both the parents and their metabolites. Exploring the use of synthetic musk fragrances as tracers of wastewater discharges in surface waters

M. Rusconi, Water Research Institute - Italian National Research Council IRSA-CNR / Water Research Institute; S. Valsecchi, M. Mazzoni, M. Di Paolo, Water Research Institute - Italian National Research Council IRSA-CNR; S. Polesello, Water Research Institute - Italian National Research Council IRSA-CNR / Water Research Institute

Traces of almost all the substances consumed by humans or released by anthropic and industrial activities end up in the environment and if measured in the different environmental compartments can give some information on their sources. The need for determining the contribution of the different sources of contamination in a polluted and urbanized area in Northern Italy drove us to search for tracers of specific sources in order to find a quantitative correlation with specific human activities. Anthropogenic compounds previously suggested as potential wastewater indicators include artificial sweeteners, persistent drugs, and personal care products. Since each of these tracers has different uses, human metabolism and transformation pathways in natural systems or in treatment plants, the simultaneous analysis of different tracers with their metabolites and transformation products under different hydrological and precipitation regimes can be a powerful mean to assess the relative contribution of different sources and processes. In the framework of a wider project aimed to compare different urban tracers, we developed and tested an Isotope Dilution GC-MS method for the analysis of synthetic musk fragrances in waste and surface waters. Synthetic musks are widely used as fragrances additives in many consumer products, they are widely present in the environment and they tend to accumulate in sediment, sludge and biota. The method, validated taking carefully into account the problem of blank contamination, allows to determine 9 compounds, including nitro-, polycyclic-, macrocyclic musks and a transformation product (galaxolide lactone), which can be a specific tracer of WWTP discharge. The occurrence of this class of substances has been evaluated in the river Po basin, which is an area with a very high pressure from population, industry and intensive agriculture, through specific campaigns that will be designed to evaluate their suitability as markers of anthropic pollution. Treated wastewater from wastewater treatment plants of Milano and Monza, surface waters (River Lambro and Lambro Meridionale) and irrigation waters has been included in the analytical campaign to assess the overall mass balance of the selected tracers.

National Environmental Specimen Bank of Norway

M.V. Dimmen, Norwegian Environment Agency; E. Farmen, The Norwegian Environment Agency; E. Lie, E. Fjeld, NIVA Norwegian Institute for Water Research

The modern society are probably using chemicals today that will be regarded as pollutants in the future. The samples stored in Environmental Specimen Bank (ESB) Norway can be used to identify the presence and/or biological effects of such substances in the environment alongside development of new analytical methods for detection. ESB Norway contains frozen samples of animals, plants, air and mud from across Norway and the Arctic. Sample collection is coordinated with routine monitoring programmes, ensuring a consistent sampling strategy and possibility to correlate currently monitored parameters to future results. During 2016, the bank will open for applications for sample acquisition for the first time, marking the starting point of new knowledge as the interest rate from stored samples.

MO029

Transfer of POPs from amendments to agricultural soils

L. Lundin, Department of Chemistry; P. Haglund, Umea University / Department of Chemistry

Recycling organic waste as soil amendments is beneficial for organic matter, soil organisms and soil structure. The ECOSOM project study the effects on soil related to application of different organic wastes or amendments. Studies on persistent organic contaminants (POPs) are important since there is an interesting and complex interplay between organic contaminants and soil organic matter. In this project soil at two French sites have been amended with composted municipal solid waste, composted biowaste, composted sewage sludge and farmyard manure and soil at two Swedish sites were amended with sewage sludge or compost. Organic waste products doses input on the different field sites in this study did exceed usual doses applied in France and Sweden. Analysis of polychlorinated dibenzo-p-dioxins and dibenzofurans (PCDD/F), polybrominated dibenzo-p-dioxins and dibenzofurans (PBDD/F), polychlorinated biphenyls (PCB) and polybrominated diphenyl ethers (PBDE) were performed on soils and amendments. Soils and amendments were Soxhlet-Dean-Stark extracted then purified and fractionated on two sequential gravity fed liquid chromatography columns, a multi-layer silica gel column and a Florisil® column. The samples were analyzed using a Waters AutoSpec ULTIMA NT 2000D high resolution mass spectrometer. Amendments used in the field trials all contained the targeted POPs, but the contents are mainly low and vary greatly between the different types of amendments and the POPs concerned. Sewage sludge had the highest combined toxic potential (of PCDD/F, PBDD/F and WHO- PCBs) at 20 ng WHO-TEQ kg^{-1} amendment. The concentrations of the targeted POPs increased in most amended soils at the four field sites. However, the observed increase were inferior to the flows of POPs provided by the amendments. This may be explained by the degradation of the compounds, their interaction with soil organic matter which render them unrecoverable or their transport into deeper soil layers. However, the results from one of the field sites in Sweden differ from the other field sites in the study. It was the only site were the combined toxic concentration increased. The increase were 12 times, 36±1.4 ng WHO-TEQ kg^{-1} soil compared to 3.1±0.5 ng WHO-TEQ kg^{-1} soil in the control soil. All the targeted compounds, PCDD/F, PBDD/F, PCB and PBDE have increased in concentration with 14, 2, 85 and 68 times since the establishment in 1956 compared to the concentrations in the control soil today.

MO030

Determination of Rodenticides in Fish Samples of the German Environmental Specimen Bank

M. Kotthoff, Fraunhofer IME / Environmental and Food Analysis; H. Jürling, M. Bücking, Fraunhofer IME   Institute for Molecular Biology and Applied Ecology

For the determination of eight rodenticides in fish muscle and liver an appropriate method was adap¬ted. Initial analyses revealed that higher concentrations were detected in fish liver as compared to fish filet. Thus the method was further optimized for liver samples and validated. The final protocol applied high-resolution mass spectrometric detection and yielded a limit of quantification (LOQ) of 0.06 µg/kg wet weight for most compounds (validated by repeated measurements). Applying the final method to bream liver samples from the German Environmental Specimen Bank (ESB), Bromadiolone, Flocou¬mafen, Brodifacoum, and Difethialone were found at levels > LOQ. In a further step, bream liver samples from the ESB archive sampled at 17 sites across Germany were analysed retrospectively. In this spatial comparison for the year 2011, highest levels were found at the site Saar / Rehlingen: 0.8 µg/kg Bromadiolone, 4.6 µg/kg Brodifacoum, 4.0 µg/kg Difethialone. These three compounds were the only identified rodenticides. Brodifacoum was the most frequently detected rodenticide at all test sites (found at 10 of 17 sites). The other rodenticides occurred rarer (Bromadiolone at 3, Difethialone at 7 locations). Difethialone reached a concentration of 4.0 µg/kg in bream liver from the site Saar / Rehlingen. Based on the results of the rodenticide spatial screening, samples from Saar / Rehlingen and Elbe / Prossen were chosen for a temporal comparison. From both sites, ten bream liver samples from the ESB archive were retrospectively analysed (years 1992 to 2013). Examining the results, no clear trend can be observed, but year-to-year changes in rodenticide loads. Again, Brodifacoum was the most frequently detected rodenticide (detected in almost every investigated year at Elbe / Prossen), and the most abundant one (levels of up to 4.6 µg/kg at the site Saar / Rehlingen 2011). Bromadiolone was found only in some years (up to 1.8 µg/kg, Elbe / Prossen 2003). Difethialone was detected only in some years (up to 4.0 µg/kg bream liver, Saar / Rehlingen 2011).

MO031

The impact of natural and anthropogenic Dissolved Organic Carbon and pH on the toxicity of triclosan to Gammarus pulex

S. Comber, Plymouth University / Environmental Science; C. Rowett, Plymouth University; T. Hutchinson, School of Biological Sciences, Plymouth University / School of Biological Sciences

Routine ecotoxicology testing rarely accounts for the effect of natural water chemistry on chemicals bioavailability. Therefore, this study identifies whether key omissions in relation to Dissolved Organic Carbon (DOC) and pH have an impact on calculated effect concentration (EC) values. Laboratory ecotoxicology tests were undertaken for the widely used antimicrobial compound triclosan, using wild Gammarus pulex. These tests were undertaken in synthetic fresh water, humic acid solutions and wastewater treatment works effluent at mean pH values of 7.3 and 8.4. G. pulex immobilisation and triclosan concentrations were measured and used to calculate 24 and 48 hour EC values. The results showed that toxicity tests undertaken at a pH above triclosan's pKa and in the presents of humic acid and effluent, containing 11 and 16 mgl^{-1} mean DOC concentrations respectively, resulted in decreased triclosan toxicity. This was most likely a result of varying triclosan speciation and complexation, due to its pKa and high hydrophobicity controlling its bioavailability. The mean 48 hour EC50 values calculated under different conditions varied between 0.75 and 1.93 mgl^{-1}. These results demonstrated that both pH and DOC can have a statistically significant effect on triclosan's toxicity. This suggests that standard ecotoxicology tests can cause inaccurate estimations of triclosan's bioavailability and subsequent toxicity in natural aquatic environments. This could result in tests overestimating toxicity, causing overly stringent Environmental Quality Standards. These results highlight the need for further consideration regarding the role that water chemistry has on the toxicity of organic contaminants and how ambient environmental conditions are incorporated into the standard setting process in the future.

MO032

Sun light enhances toxicity of methyl paraben and 1,2-hexanediol to Daphnia magna and Danio rerio embryo

j. Lee, Yongin University; K. Lee, Seoul National University / Graduate School of Public Health; K. Ji, Yongin University

Methyl paraben (MP) has been widely used as antimicrobial preservatives in cosmetics, pharmaceuticals and food products, and 1,2-hexanediol (1,2-H) has been applied for cosmetics as an alternatives of paraben. However, very limited information has been reported on the phototoxicity of these chemicals among aquatic organisms. In the present study, acute toxicities of MP and 1,2-H were evaluated using Daphnia magna (48 h exposure) and Danio rerio (96 h exposure) embryos. We also investigated whether phototoxicity of MP and 1,2-H would be affected by environmental level of ultraviolet lights, i.e., exposure to 4 h/d sunlight. Changes in expression of genes related to oxidative stress were determined in D. magna juveniles after being exposed to sublethal levels of the chemicals and environmental level of ultraviolet lights. Greater toxicities were observed with MP and under environmental level of ultraviolet lights in both species. In D. rerio embryos, exposure to MP resulted in lesser rates of hatching and increased malformation rates. Expressions of hemoglobin and α-esterase genes in D. magna were increased by co-exposure to MP and to ultraviolet lights. Our experiments demonstrated that exposure to MP led to oxidative damage in aquatic organisms and it was aggravated by natural ultraviolet lights. Further assessment for sublethal effects and specific mechanisms of MP under environmentally relevant conditions should be followed. Keyword: Phototoxicity, methyl paraben, 1,2-hexanediol, ultraviolet light, oxidative stress

Evaluation of decamethylcyclopentasiloxane (D5) accumulation behavior in Herring gull eggs from the Oslofjord urban environment

N.A. Warner, NILU - Norwegian Institute for Air Research / Environmental Chemistry; A. Ruus, NIVA / NIVA; L. Hanssen, L. Christoffersen, NILU Norwegian Institute for Air Research; M. Heldberg, University of Oslo

Since its initial detection within the Oslofjord in 2005, decamethylcyclopentasiloxane (D5) has been the focus of monitoring and regulatory activities over the past several years. Through the combination of high production/use and hydrophobicity/lipophilicity, accumulation of D5 in aquatic environments (e.g., sediment, biota) have not only been observed in the Oslofjord, but many other aquatic ecosystems impacted by human activities and waste. Aquatic species are considered to be at greatest risk to cVMS exposure due to exposure through sediment compartments and lower elimination capabilities. Monitoring and research focus has mostly been placed on aquatic environments as cVMS accumulation potential in air respiring organisms is considered low due to high elimination through metabolic degradation and respiration processes. However, recent findings under the "Environmental Contaminants in an Urban Fjord" program of the Norwegian Environmental Protection Agency showed elevated levels of cVMS within Herring gull eggs collected from the Oslofjord region. Concentrations of D5 detected in Herring gull eggs collected in 2013 (51.6 ± 71.8 ng/g wet weight (ww)) and 2014 (61.4 ± 51.7 ng/g ww) were comparable with maximum concentrations reaching 265 ng/g ww. Similar levels were observed for PCB 153 in 2013 (130 ± 96.2) and 2014 (75.8 ± 75.1 ng/g ww), indicating substantial uptake of D5 from the surrounding environment. High variation in ^{15}N stable isotope signatures indicates a variable eating pattern among mother birds. In addition, both ^{13}C and ^{15}N stable isotope signatures were not reflective of the local aquatic food web, indicating feeding of the mother birds has occurred elsewhere. Low ^{13}C and ^{15}N stable isotope signatures in Herring gull eggs may indicate greater feeding from terrestrial based carbon sources for energy. As opportunistic feeders, Herring gulls are known to scavenge on human waste, which are highly contaminated with volatile siloxanes and may represent an important source of D5 exposure to seabirds. Although air breathing organisms are considered to be of low risk for the bioaccumulation of D5, results presented here indicate D5 acumulation occurs within herring gull eggs. This is may indicate a potential risk to un-hatched birds and should be further monitored.

MO034

Emerging pollutants in reclaimed water. Is there some concern about crop irrigation?

E.M. Beltrán, INIA - National Institute for Agricultural and Food Research and Technology / Environmental; C. Fernández, National Institute for Agricultural and Food Research and Technology / Department of Environment Laboratory for Ecotoxicology; M.A. Porcel, J. Pro, M. Torrijos, INIA   National Institute for Agricultural and Food Research and Technology / Department of Environment Laboratory for Ecotoxicology; G. Carbonell, National Institute for Agricultural and Food Research and Technology / Department of Environment Laboratory for Ecotoxicology

Reclaimed water is a strategic effective way to help solve the problem of water scarcity and droughts in the EU. In 2009 in Spain, the current level of water reuse was estimated to be about 500 Mm^3 (Spanish Ministry of the Environment). It is predicted that wastewater reuse in Europe will be 3,222 Mm^3/year by 2025, with Spain in first position (over 1,200 Mm^3/year). Agricultural irrigation is the main application in many EU countries and accounts for around 33% of total water use (EEA, 2012), although this figure comes close to 60% in certain regions of Spain. In this work, reclaimed water samples supplied by a Spanish WWTP were used to analyse the presence of 44 emerging pollutants (pharmaceuticals, parabens and endocrine disruptors). Different microcosms and semi-field studies were performed with three crops (lettuce, corn and radish) irrigated with spring water, reclaimed water and fortified (atenolol, carbamazepine and triclosan,) reclaimed water (at 10 and 100 higher levels than the mean observed in reclaimed waters). The aim was to assess possible adverse effects of emerging pollutants on soil-plant systems caused by reclaimed water. The experimental results evidenced no variations in soil functionality, pigments content in leaves or accumulation of emerging pollutants in different plant parts compared to those irrigated with spring water. This work was possible thanks to Spanish Government Grants CTM2013-44986-R and CTM2014-52388-R.

Use of Watson Database for prioritization of pharmaceuticals in Dutch effluents of WWTP's: a case study

B.J. Pieters, The Water Laboratory; N. van Duijnhoven, E. Roex, DELTARES; R. Berbee, Dutch Ministry of Infrastructure and Environment; S. Mol, The Water Laboratory

Dutch surface waters are polluted by a wide range of micro pollutants originating from several diffuse and point sources. Especially emerging compounds (EC's) may pose an ecological and human health risk, even at low concentrations. Nonetheless, relevant EC's are often not regulated with threshold values in surface waters up till now. Furthermore, basic information on ecotoxicity, concentrations and loads are often lacking. This hampers the realisation of reduction plans for emissions and therefore mitigation of risks. The effluents of Waste Water Treatment Plants (WWTP's) are identified as an import point source of EC's such as organic micro pollutants, pharmaceuticals, personal care products and illicit drugs. The Dutch Ministry of Infrastructure and the Environment therefore assembled a database containing approximately 174.000 chemical measurements (1990-2015) of 1.010 compounds in influents and effluents of 150 WWTP's. The Watson database is updated once every 3 years with measurements from regular monitoring and pilot investigations. Compounds include predominantly organic micro pollutants, but metals as well. This so called Watson database is readily available for water managers and offers estimations of concentrations, loads and removal rates of WWTP's as input for water models and thus decision making. Human pharmaceuticals are an important group of EC's and are currently investigated in The Netherlands as part of a chain approach to reduce emissions from WWTP's. The Watson database contains information on 205 different pharmaceuticals. To demonstrate the usability of the Watson database, an exercise was performed to calculate estimates for the year 2015 of concentrations and loads in effluents and removal rates of WWTP's in order to prioritize pharmaceuticals for regulators. Estimates of loads were scaled up to a national level. Furthermore, the potential environmental risk of pharmaceuticals was estimated by dividing the effluent load by the Defined Daily Doses (DDD) of pharmaceuticals as described by the WHO. Due to the overall lack of ecotoxicity data of pharmaceuticals, DDD values may act as an appropriate surrogate as they describe the therapeutic activity and thus general toxicity of pharmaceuticals. The exercise provided valuable information for both water managers and regulators to make cost-effective choices by first tackling those pharmaceuticals with the highest effluent loads and toxicological risks.

MO036

Episode study of pharmaceuticals and personal care products from urban effluents

Y. Lin, Norwegian Institute for Water Research NIVA; L. Nizzetto, NIVA Norwegian Institute for Water Research; O. Sáňka, Research Centre for Toxic Compounds in the Environment RECETOX; J. Kalina, Masaryk University Faculty of Science RECETOX; J. Becanova, Masaryk University / RECETOX Research Centre for Toxic Compounds in the Environment

Pharmaceuticals and personal care products (PPCPs) as well as their metabolites are contaminants of emerging concern and have been frequently detected in the environment. Their real impact on biota are unknown. Urban effluents are important sources for PPCPs. Their fate and transport in the environment (in particular riverine transport) is not easily traceable since they degrade through both chemical and biochemical reactions and can interact with dissolved and particulate phase in water. Fate and transport are therefore dependent on river characteristics and hydrological regime. It is not clear how extreme high flow events influence emissions and transport of PPCPs. Urban effluents and riverine concentrations from a mid-sized European city (Brno City, Czech Republic) were sampled at high resolution (every two hours) and analyzed for a range of PPCPs during both normal flow and an intense rainfall event. Collected data were used to constrain the hydrobiogeochemical/multimedia contaminant fate model INCA-Contaminants. The model was then used to track PPCPs transport along space and time in the river network.

MO037

Designing a Quality Control Program for Collection and Analysis of Siloxane samples from Environmental Monitoring Programs

J.A. Durham, Dow Corning Corp. / Health and Environmental Sciences; N.A. Warner, NILU - Norwegian Institute for Air Research / Environmental Chemistry; S. Knoerr, R. Seston, D. Powell, Dow Corning Corp

When embarking on an environmental monitoring study, it is critical that the proper quality control (QC) parameters are evaluated to ensure integrity of the results obtained from monitoring activities. This is especially critical when analytes under investigation can be present in personal care products, equipment and analytical instrumentation as is the case for cyclic siloxanes. Selecting an appropriate QC matrix is imperative to accurately account for loss or contamination during collection, transport, and laboratory processing and analysis. In addition, it is important to evaluate analytical variation introduced by the sample matrix itself to the overall signal measured to avoid reporting false positives. It is therefore important that QC matrices be determined prior to the initial design of the monitoring program. Key aspects when designing a QC program include applying an appropriate QC matrix which matches or mimics the sample matrix being collected; determining background contribution from sample collection and laboratory equipment; evaluating initial concentrations present within QC matrices prior to application and how they will evaluate analyte loss or contamination. This presentation will provide an overview of quality control evaluations from several different programs and the best practice for creating a proper QC program. The Loss and contamination of the analyte in the field has been assessed using a variety of materials including fish muscle/liver, sediments and sorbents such as low density polyethylene and XAD® resin. Additionally, processing and analysis QC are assessed to evaluate contamination from equipment such as collection and analysis jars, use of nitrogen as well as analysis equipment.

MO038

Determination of toxic effects of environmental contaminants on gap junctional intercellular communication in TM3 Leydig cell line

A. Yawer, RECETOX, Faculty of Science, Masaryk University / TOxicolgy; P. Macíková, Masaryk University Faculty of Science RECETOX; P. Babica, Masaryk University, RECETOX / RECETOX; I. Sovadinova, Masaryk University
Yawer A., Macíková P., Babica P. Sovadinová I. *RECETOX, Masaryk University, Kamenice 753/5, 625 00, Brno, Czech Republic* Environmental contaminants are substances that, when accidentally or deliberately introduced into the environment, might induce adverse ecological or health effects. Male reproductive system is uniquely vulnerable to such toxic chemicals in the environment. It has been hypothesized that exposures to environmental toxicants is responsible for increasing incidence of congenital malformations of the reproductive organs and testicular cancer, deteriorating semen quality, and decreasing sperm counts, which has been reported in the past decades. Disruptions of hormonal regulation by so-called endocrine disrupting chemicals (EDCs) have been suggested as one of the principal mechanism underlying adverse effects of toxicants on male reproductive system. However, homeostasis balance, morphogenesis, cell differentiation and growth in testicular tissues are physiological processes strictly regulated by gap junctional intercellular communication (GJIC), a process known to be altered by various environmental contaminants, including well-recognized EDCs. We are currently investigating (i) the effects of selected EDCs as well as personal care products (PCPs) on GJIC inhibition in mouse somatic testicular cells, TM3 Leydig cell line, and (ii) which mechanisms are involved in dysregulation of GJIC. The results showed that organochlorine pesticides (methoxycholor, lindane and DDT), and PCPs (triclosan and triclocarban) induced rapid (30 min) dose-dependent inhibition of GJIC in TM3. The effects became more pronounced after 6 or 24 h exposure, where significant reduction of GJIC was induced also by bisphenol A, vinclozolin and PCB153. As determined by Western blotting analyses, the inhibition of GJIC was accompanied by activation of mitogen activated protein kinase ERK1/2, which is the mechanism implicated in GJIC dysregulation induced by known tumor promoters, e.g. 12-O-tetradecanoylphorbol-13-acetate (TPA). Inhibition of GJIC and activation of MAPKs were observed at the concentrations of chemicals not associated with cytotoxic effects as evaluated by Neutral Red uptake, Alamar Blue and CFDA-AM assays. Our results indicate that EDCs and PCPs might disrupt testicular homeostasis and functions via alterations of GJIC and MAPKs.

Performing a large scale survey of xenobiotic removal efficiencies of activated sludge treatment plants with a cost-efficient sampling scheme in Luxembourg

T. Gallé, Luxembourg Institute of Science and Technology (LIST) / ERIN; C. Koehler, M. Plattes, M. Bayerle, D. Pittois, Luxembourg Institute of Science and Technology LIST

Xenobiotic removal by activated sludge treatment plants can be very variable depending on the design and the operational parameters of the sites. Accurate full scale balances are cumbersome to realize and laboratory sludge experiments have not been related to overall plant performance with enough cases for statistical relevance. Therefore the EmiPoll project has been launched in Luxembourg to evaluate the performance of activated sludge treatment plants with an array of techniques. Full scale plant balances will be performed with passive samplers covering an entire week of inflow vs. outflow. This approach circumvents the problem of mixing regimes and matching volumes in classical autosampler campaigns through the extended time-period of observation. Although for reasons of different suspended matter and DOC loads at the in- and outlet the sampling rates of the passive samplers are different, this can be normalized by conservative substances like f.ex. carabamazepine or lidocaine. The ease of operation allows a multitude of plants to be monitored in parallel with much less workload than autosampler campaigns. The contribution will shed a critical view on the clogging of membranes of passive samplers and the representativeness of sampling in both in- and outlet with this approach. In addition the campaign features laboratory analyses including respirometric tests of the activated sludge, enzyme assays and degradation kinetics of selected substances. The goal is to compare the performance of a large amount of WWTPs (24 sites) and relate the elimination efficiencies with plant design and operational settings. Prioritisation of advanced treatment or leeway in operational improvement will be explored within this project. This contribution presents the results of a first part of the campaign.

MO040
Development of a counter-current chromatography-based extraction method for emerging contaminants
B. Huerta Buitrago, Catalan Institute for Water Research (ICRA) / Institute of Environment Health and Societies; A. Pathmanathan, University Pierre et Marie Curie; M.D. Scrimshaw, Brunel University London / Institute for the Environment; S. Ignatova, Brunel University London
Complex mixtures of emerging pollutants which include pesticides, biocides, personal care products and pharmaceuticals are constantly present in the hydrosphere and may pose a risk to aquatic ecosystems and human health. The vast and ever-increasing number of chemicals, often present at very low (sub ng/L) concentrations, complicates their monitoring and subsequent regulation. In this context, we propose the application of high performance counter-current chromatography (CCC) as a novel tool for the extraction of a broad variety of pollutants from river waters. CCC is a chromatographic separation technique that has become a novel, worldwide separation and purification technique and is based on the partition of compounds between two immiscible liquid phases as they interact in a thin tube under a fluctuating centrifugal force field. The research explores the use of CCC, not as a separation technique, but as an extraction method for large volumes of water. The extraction is based on partitioning between the two immiscible liquid phases: the mobile phase and the stationary phase. The mobile phase is the water sample potentially containing the pollutants, while the stationary phase is an appropriate organic solvent(s), retained in the column by centrifugal rotation. The advantages of this technique range from little to no sample preparation, and highly versatile solvent systems, to high recovery efficiencies and potentially unlimited extraction capacity. We have applied this powerful tool for the extraction from water samples of a number of compounds, including pesticides, pharmaceuticals, and corrosion inhibitors, covering a wide variety of polarities (log K_{ow} between 1 and 5). Preliminary results demonstrating a range of recovery efficiencies for the majority of these compounds and method development will be presented and discussed.

MO041
The consortia of microorganisms for use in bioremediation
A. Wysocka, M. Popowska, University of Warsaw, Faculty of Biology / Institute of Microbiology Department of Applied Microbiology
The continuous development of the industry results in the appearance of chemical compounds in the environment, which do not occur in nature. The different types of them and their metabolites are highly toxic and constitute a threat to humans – some of them are potent poisons, often exhibiting strong mutagenic and carcinogenic properties. Most of the aromatic compounds are characterised by stability and durability in biological systems, and what is more, considerable resistance to degradation. An additional concern is that the contamination of the soil by xenobiotics, is also a direct threat to groundwater, and consequently may result in the penetration of these pollutants into flowing waters. The problem of soil and groundwater contamination by xenobiotics from various branches of industry, concerns not only Poland and other European Union countries, but practically all industrialized world. The main objectives of our study were characterisation of microorganisms (bacteria and fungi) isolated from several environments polluted with petroleum compounds, heavy metals, impregnates for wood and the other xenobiotics. All soil samples were analyzed for the presence of pollutants: heavy metals, PAHs, BTEX, gasoline and mineral oils. The bacterial strains and fungi were identified by PCR amplification and characterised for their ability to degrade certain hazardous substances, for instance mazout, other petroleum compounds and antibiotics in the presence of heavy metals. Assessment of the degradation rate of each pollutant may help to choose those strains, which play the critical role in this process. Selected ones will be part of consortium, which in future might be commercially available as biovaccine. Currently, preliminary studies on this subject has been launched in laboratory systems - microcosms. This approach enable us to test different variants of our study and define optimal relative content of each culture, as well as abiotic conditions. This method in easy and eco-friendly way of removing hazardous pollutants from the environment without introducing any synthetic products into it. The in situ bioremediation is based on natural processes occurring in the environment, which is associated with considerably lower costs than conventional physicochemical methods. The developed and deposited composition of strain (biovaccine) provides a possibility to quickly obtain the appropriate amount of the formulation and conduction of bioremediation in a short time.

MO042
Ecotoxicological endpoints to assess the impact of nanomaterials on soil and water biota
S. Sanchez-Fortun, UCM; G. Costa, Universidad Complutense de Madrid; G. Mengs, Natural Biotec; C. Fajardo; M. Nande, UCM; M. Martin, Universidad Complutense Madrid
Heavy metals are ubiquitous pollutants worldwide. The accumulation of metals in the environment from anthropogenic sources creates the potential for significant human exposures and subsequent health hazards. Deleterious metal-induced health effects have been reported in all body systems, with exposure stemming from multiple sources, including water, air, or soil. Nanotechnology is a rapidly growing area of study with applications in numerous fields because engineered nanoparticles (NPs) unique physical and chemical properties allow them to have higher reactivity than larger particles with the same chemical composition. For the last decade, nanosized zero-valent iron (nZVI) has been used for the remediation of polluted soil, groundwater and wastewater, targeting a wide variety of common environmental contaminants, such as chlorinated organic solvents, organochlorine pesticides, polychlorinated biphenyls, inorganic anions and heavy metals. To this respect, the ecotoxicological assessment of the potential effects of the interaction nZVI-heavy metal on different organisms is an important approach to be considered. Thus, the choice of optimal species as well as sensitive ecotoxicological endpoints may allow the use of shorter testing intervals in the analysis of the interaction NP-heavy metal effects on water and terrestrial organisms. In the present study, we analyze the effects of the interaction NPs (2.5 and 5%) with different concentrations of Cd, Pb and Zn (heavy metals with persistent presence in soil and water) on several species including the green algae *Scenedesmus intermedius* and the cianobacteria *Microcystis aeruginosa*, as representative aquatic biota from fresh ecosystems, and the nematode *Caenorhabditis elegans* as representative terrestrial organism from soil ecosystems. The results in both aquatic and terrestrial organisms showed that selected toxicity endpoints (growth, reproduction, survival and photosynthetic activity) were significantly affected by the heavy metal concentration used. However, these effects were reverted by the presence of nZVI in all cases. Together, these results suggest that: 1) the organisms as well as the endpoints considered have shown to be suitable to analyze the ecotoxicological effects of metal and nZVI interactions, and 2) nZVI have shown to be an excellent method to heavy metal immobilization thus rendering their deleterious effects and making nZVI as an excellent tool in the remediation of contaminated ecosystems.

MO043
THE UKWIR Chemicals Investigation programme Phase 2, 2015-2020
M.J. Gardner, V. Jones, Atkins Ltd; D. Leverett, WCA-Environment Ltd
The UKWIR Chemicals Investigation Programme is the response of the UK water industry to current and emerging legislation on trace substances in surface waters. The first phase of the Programme (CIP1 - 2010-2013) was aimed at the prioritisation of compliance risks posed by different substances and determination of their sources. It provided a generic overview of trace contaminant concentrations in wastewater treatment works effluents and the effectiveness of current treatment processes in reducing contaminant concentrations. The second phase of the CIP is now under way. This £140M programme of monitoring and investigations is focussed on: site-specific compliance status at over 600 wastewater treatment works; the demonstration of where there is a clearly justifiable need for action/investment; and, the potential improvements in effluent quality that might be offered by various novel treatment processes. Participants and contributors include all water companies in England, Wales and Scotland, Defra, Environment Agencies, Ofwat, Atkins Limited, wca-environment and Plymouth and Cranfield Universities. This poster summarises the scope and aims of this ambitious programme and presents some initial results for Water Framework Directive Priority Substances and Specific Pollutants. Results indicate that compliance status might be at risk at the majority of sites for a limited number of specific substances. This implications of this will be discussed.

MO044
Development of a LC/MS/MS method for the comprehensive assessment of of macrolide antibiotics in the aquatic environment
I. Senta, I. Krizman, S. Terzic, Rudjer Boskovic Institute; M. Ahel, Rudjer Boskovic Institute / Division for Marine and Environmental Research
Macrolide antibiotics are among the most popular types of antimicrobials. As a concequence, a number of studies in the literature addressed the issue of environmental exposure to these emerging contaminants in municipal wastewaters and ambient waters. Macrolide antibiotics are released from the human body after therapeutic application mainly unchanged, however, several literature reports indicated that macrolides can be transformed in the environment either via

microbial or photochemical degradation, yielding a number of transformation products. Nevertheless, most of the existing exposure data refer only to the parent compounds, while the information on possible macrolide intermediates and/or transformation products in the aquatic environment are very scarce. One of reasons is the lack of analytical methods for the comprehensive assesment of macrolide-derived compounds in aqueous samples. Therefore, the aim of this work is to develop a multiresidue method for the simultaneous determination of several prominent macrolide antibiotics (azithromycin, clarithromycin, erythromycin and roxithromycin) along with their intermediates and transformation products using liquid chromatography tandem mass spectrometry (LC/MS/MS). The method development comprised improvement of the chromatographic separation of macrolide compounds using a new type of reversed-phase stationary phase, which combines octadecyl and phenyl moieties, and optimization of enrichment of target compounds from aqueous phase using Oasis HLB and mixed-bed stationary phases. The developed method was employed for the analysis of macrolide-derived residues in real wastewater and ambient water samples, collected in the area of the city o Zagreb. It was shown that intermediates and/or transformation products significantly contribute to the overall mass balance of macrolide-derived compounds. This indicates that the risk associated with the use of macrolide compounds in the aquatic environment should include assessment of possible effects caused by their transformation products and intermediates from their production.

MO045

Comparison of pharmaceutical discharges and treatment from hospital and domestic sources

L. Wiest, Institut des Sciences Analytiques / TRACES; A. Bergé, R. Baudot, Institut des Sciences Analytiques / TRACES Team; M. Sordet, E. Vulliet, Institut des Sciences Analytiques / UMR Equipe Traces rue de la Doua Villeurbanne France

Chemical water pollution is more and more studied and documented. Among the most studied pollutants, drugs are special contaminants, due their very low concentrations in the environment and the potential presence of metabolites. Even though effluents from sewage treatment plants are well known to be one of the major sources for introduction of pharmaceuticals into the aquatic system, contributions of significant sources such as hospitals or agriculture are still unclear. Furthermore, despite their high solubility in water, their partition can be significant in the suspended solid phase, although this fraction is not always analysed. In this context, this work consists in a long-term study of hospital and urban effluents and their treatment. Target substances include analgesic, anti-inflammatory, antihypertensive, hormonal contraceptive, antibiotic, anti-fungal, anti-convulsant products and metabolites. Thanks to the use of advanced analytical techniques, limits of quantification consistent with ultra-traces detection were achieved. All the pharmaceuticals analysed were detected. Two molecules, econazole and ethinylestradiol were only detected in the suspended solid phase, which shows the importance of analysing this fraction. Three pharmaceuticals were present at significantly higher concentration in the hospital influent: ketoprofen and two antibiotics: ciprofloxacin and sulfamethoxazole. . Metabolites analysis highlighted the presence of the 4-hydroxy diclofenac and the N4-acetylated sulfamethoxazole at concentrations close to those of the parent molecules. Regarding the water treatment, all pharmaceutical removals were above 50%, except for carbamazepine and diclofenac. Contrary to what was expected, removals were higher with the hospital influent, may be due to the difference of hydraulic residence time. Finally, sludge analysis revealed the presence of eight pharmaceuticals. Among them, three were quantified at concentrations higher than 1 μg/g: diclofenac, ciprofloxacin and more surprisingly salicylic acid, as this molecule is more polar than the others. Thanks to a large number of campaings, this work allowed to acquire consolidated data on the occurrence of pharmaceuticals in hospital and urban wastewaters and their removal. This study also highlights the importance of considering understudied parameters, such as the suspending solid phase and metabolites, for a better understanding of the pharmaceutical fate in the environment.

MO046

Selection of the most environmentally benign ionic liquids option by coupling OECD standardized tests and fish leucocyte mortality

A. Bado-Nilles, INERIS; L. Chabot, INERIS / EXES; G. Marlair, INERIS; S. Jolly, Université Technologique de Compiègne; J. Porcher, INERIS / INERIS UMRI SEBIO ECOT; P. Pandard, INERIS

To reduce health and environmental risks of chemicals and to minimize the environmental footprint of human activities, green chemistry searches for alternative, environment-friendly reaction media and at the same time strives to increase reaction rates and milder reaction conditions. A growing area of research is devoted to ionic liquids (ILs) often termed as "designer" solvents due to the extreme tunability of sought functional properties. As the aftermath of earlier misleading messages reporting ILs generically as intrinsically "safe and risk free" whatever ILs considered, their increase in potential or emerging applications in key domains (like bio-refining, energy storage, nano-material processing, pollution remediation…) dictates a more scientifically-sound approach of actual risk profiles of ILs, including both physico-chemical, health and environmental risks that might be triggered by inadequate selection of use of ionic liquids. In this context, we proposed a advanced approach serving comprehensive evaluation of environmental hazard by combined use of OECD standardized tests (*Daphnia magna* acute immobilization test ; algal growth inhibition test) and fish ex vivo leucocyte mortality analysis. This innovative approach integrating multicriteria assessment has been tested to on a first set of seven imidazolium-based ([BMIM][Cl], [EMIM][Cl], [EMIM][DCA], [EMIM][MeSO3], [EMIM][EtOSO3], [EMIM][BF4], [HMIM][Cl]) and four phosphonium-based ionic liquids ([P6,6,6,14][Cl], [P6,6,6,14][DCA], [P6,6,6,14][(iC8)2PO2], [Pi4,i4,i4,1][TOS]) and is expected to be further used to examine other ILs (biobased, ILs, pyrrolidinium, …) in soon future. Results of ecotoxicity tests obtained so far have revealed a clear potential to rank clearly the families of ILs according to the studied risk and even to identify influencing structural factors within a same family of ILs and compounds within the same family. Complementarity of these tests and ecotoxic properties of IL will be discussed specifically in terms of ecological footprint reduction strategies in chemical engineering processes for successful IL utilization in the future.

MO047

Emerging pollutants in reclaimed water. Is there some concern about crop irrigation?

E.M. Beltrán, INIA - National Institute for Agricultural and Food Research and Technology / Environmental; C. Fernández, National Institute for Agricultural and Food Research and Technology / Department of Environment Laboratory for Ecotoxicology; M.A. Porcel, J. Pro, M. Torrijos, INIA National Institute for Agricultural and Food Research and Technology / Department of Environment Laboratory for Ecotoxicology; G. Carbonell, National Institute for Agricultural and Food Research and Technology / Department of Environment Laboratory for Ecotoxicology

Reclaimed water is a strategic effective way to help solve the problem of water scarcity and droughts in the EU. In 2009 in Spain, the current level of water reuse was estimated to be about 500 Mm^3 (Spanish Ministry of the Environment). It is predicted that wastewater reuse in Europe will be 3,222 Mm^3/year by 2025, with Spain in first position (over 1,200 Mm^3/year). Agricultural irrigation is the main application in many EU countries and accounts for around 33% of total water use (EEA, 2012), although this figure comes close to 60% in certain regions of Spain. In this work, reclaimed water samples supplied by a Spanish WWTP were used to analyse the presence of 44 emerging pollutants (pharmaceuticals, parabens and endocrine disruptors). Different microcosms and semi-field studies were performed with three crops (lettuce, corn and radish) irrigated with spring water, reclaimed water and fortified (atenolol, carbamazepine and triclosan) reclaimed water (at 10 and 100 higher levels than the mean observed in reclaimed waters). The aim was to assess possible adverse effects of emerging pollutants on soil-plant systems caused by reclaimed water. The experimental results evidenced no variations in soil functionality, pigments content in leaves or accumulation of emerging pollutants in different plant parts compared to those irrigated with spring water. This work was possible thanks to Spanish Government Grants CTM2013-44986-R and CTM2014-52388-R.

MO048

Human health risk assessment of imidazoliun-based ionic liquids: the role of acetone to their function integrity and toxic profile

V. Tsarpali, University of Patras / Department of Biology; M. Antonopoulou, I. Efthimiou, D. Vlastos, University of Patras / Department of Environmental and Natural resources Management; I. Konstantinou, University of Ioannina / Chemistry; S. Dailianis, Univeristy of Patras / Biology

The growing interest for the use of ionic liquids (ILs) in a wide range of applications has raised great concerns about their potential environmental and health hazards. Since ILs, such as 1-butyl-3-methylimidazolium tetrafluoroborate ([bmim][BF_4]) and 1-methyl-3-octylimidazolium tetrafluoroborate ([omim][BF_4]), are widely used either pure or in mixtures with water and/or conventional solvents, such as acetone, the present study investigates their cytotoxic and genotoxic potency in cultured human lymphocytes with the use of cytokinesis block micronucleus (CBMN) assay. Moreover, the interaction of acetone with [bmim][BF_4] and [omim][BF_4] was further evaluated in order to elucidate its role in both ILs function and toxic profile. According to the results, [omim][BF_4]/water (at concentrations ranged from 0.01 to 5 mg L^{-1}) showed increased cytotoxic and genotoxic effects (in terms of % cytostasis and frequencies of micronuclei formation currently measured) on interphase lymphocytes, compared to [bmim][BF_4]/water. In addition, [bmim][BF_4]/acetone (at concentrations ranged from 0.5 to 100 mg L^{-1}) showed increased cytotoxic but not genotoxic levels, compared to those occurred at the respective concentrations of [bmim][BF_4]/water, while [omim][BF_4]/acetone showed a significant decrease of both cytotoxic and genotoxic effects on treated cells, compared to [omim][BF_4]/water. Since [omim][BF_4] appeared to be significantly more cytotoxic and genotoxic than [bmim][BF_4] and showed significant differences in the presence of the carrier solvent (acetone), the possible interactions between acetone and [omim][BF_4] was further investigated. According to preliminary data, interactions of the acetone oxygen atom with the imidazolium ring can be considered. A significant effect of acetone on the interionic interactions and consequently on the ion pair dissociation can also be proposed. Further investigation is in progress. To our knowledge, the present study showed for the first time that the toxic potency of imidazolium-based ILs, such as [omim][BF_4], greatly depend from the carrier organic solvents, such as acetone, thus providing significant information for their development, usage/application and safety.

MO049

Butylparaben and propylparaben: Acute effects on Ceriodaphnia silvestrii

M. Spadoto, Sao Paulo University / Water Resources and Applied Ecology Center; A.E. Sueitt, Federal University of Sao Carlos / Chemistry; E.M. Vieira, Sao Paulo University / Departamento de Quimica e Fisica Molecular

Emerging contaminants are compounds of natural or anthropogenic origin that can be found in different environmental compartments. They constitute potential risk to biota, affecting the growth and development of organisms exposed to them. Among the compounds classified as emerging contaminants, butilparaben and propylparaben preservatives are often used together in formulations of cosmetic and personal care products, although they may cause several deleterious impacts on biota. Hence, the goal of this study was to evaluate the acute toxic effects of butylparaben and propylparaben, using as test organism the species *Ceriodaphnia silvestrii*, which is a native Brazilian representative of zooplankton. Toxicity tests were carried out using the concentrations: 0.500; 0.750; 1.125; 1.700; 2.550; 3.800 mgL^{-1} of butylparaben and 1.00; 1.50; 2.25; 3.37; 5.00 and 7.60 mgL^{-1} of propylparaben . Acute bioassays lasted 48 hours and they were repeated five times. Results from all acute toxicity tests were subjected to probit analysis using the PriProbit Program V1.6.3 to determine EC_{50} value. The average for the EC_{50}-48h/butylparaben was 1.410 ± 0.024 mg L^{-1} and EC_{50}-48h/propylparaben was 2.98 ± 0.18 mg L^{-1}. The results indicated that *Ceriodaphnia silvestrii* was sensitive to the tested emerging contaminants and the mixture of such compounds at realistic environmental concentrations. Based on this observation and considering that parabens can affect the functioning of several species at even lower EC_{50} values, it can be concluded that additional studies are required to assist the discussions on the implementation of more strict regulations regarding the discharge of these pollutants in the environment.

Flame Retardants: Alternatives, Environmental Fate and Toxicity (P)

MO050

New flame retardants: chemical identification and properties

A. Covaci, University of Antwerp, Toxicological Center / Toxicological Center Dept of Pharmaceutical Sciences; G. Malarvannan, University of Antwerp / Toxicological Center Dept of Pharmaceutical Sciences; G. Poma, University of Antwerp, Toxicological Center / Toxicological Center; P. Kurt-Karakus, Bursa Technical University / Environmental Engineering Department

Flame retardants (FRs) are chemicals used in a wide range of commercial and household products in order to reduce their flammability. Due to recent legislation and restrictions in the use of brominated FRs, a large number of alternative FRs, mostly non-halogenated, have been introduced to the market. The main aim of this study was to investigate the chemical identity of four new flame retardants technical mixtures and to inform about their properties. For each FR mixture, 5 mg were separately dissolved in iso-octane or methanol, and after appropriate dilution, the solutions were analyzed. A combination of analytical techniques was used, such as gas chromatography-mass spectrometry (in electron impact ionization and electron-capture negative ionization modes) and liquid chromatography-mass spectrometry (with positive and negative electrospray ionization). **CETAFLAM-DB168** (Avocet) is a phosphorus-based flame retardant containing an organic phosphate (tri n-butyl phosphate - TNBP) used for textiles and fabrics in aircraft, automotives, and hotels. It allows durable flame retardant properties to be transferred to polyester yarn and fabrics by simple exhaust techniques. **CETAFLAM-DB9** (Avocet) is a phosphorus-based flame retardant containing a new inorganic phosphinate and an organic phosphate (trichloropropyl phosphate - TCPP) for polyester. It is used in the automobile, clothing, workwear, furnishings, curtains and decoration and public transport textile markets. **RUCO-FLAM PSY-E** (Rudolf Group) is an organic phosphorus flame retardant with high percentage phosphorus content used for polyester (PES) and possibly also polyacrylate (PA) polymers. **PEKOFLAM PES** (Clariant) is an organophosphorus-based non-halogenated flame retardant for use on PES and PA textiles and in many (synthetic) polymer systems with 'wash resistant' effects. It consists of a mixture of cyclic di- and triphosphonates.

MO051

Analysis of organophosphorus flame retardants by GC-MS/MS with EI and APCI ionisation techniques

W. Halloum, LUNAM Université / Oniris Laboratoire dÉtude des Résidus et Contaminants dans les Aliments; R. Cariou, G. Dervilly-Pinel, Oniris-LABERCA / Oniris Laboratoire dÉtude des Résidus et Contaminants dans les Aliments; F. Jaber, Université Libanaise / Laboratoire danalyse des composés organiques LACO; B. Le Bizec, Oniris-LABERCA / Oniris Laboratoire dÉtude des Résidus et Contaminants dans les Aliments

Flame retardants (FRs) are human-made chemicals added to consumer and industrial products for the purpose of reducing flammability. Among FRs are the halogenated FRs that may be sub-divided into brominated (BFRs) and chlorinated FRs as well as phosphorus-containing FRs (PFRs). Some halogenated FRs have proven to be persistent, bioaccumulative and toxic to environment, animals and humans. This led governments to adopt restrictions (e.g. for some BFRs). On the other hand, novel brominated flame retardants (NBFRs) and organophosphorus flame retardants (OPFRs) are proposed as alternatives for historical BFRs and their use is in continuous increase. Most OPFRs are introduced as additives and not chemically bound to the polymer; hence they are slowly released in the environment by abrasion and volatilization. Although insufficient toxicity data were available on their toxicity, adverse effects were reported for some of these alternative compounds. The focus of this work was to develop and to optimize an analytical strategy enabling the identification for 18 OPFRs of which 13 are non-halogenated (TEP, TPrP, TiBP, TnBP, TBEP, TEHP, TPP, EHDPP, o-TCP, m-TCP, p-TCP, DPhBP and BPhP) and 5 are halogenated (TCEP, TDCIPP and TCPP for clrinated; TDBPP and TTBNPP for brominated) in fish muscle. The investigated preparation procedure based on pressurised liquid extraction with the in-cell use of Florisil as a first cleanup step (~65% of lipids removal). Gel permeation chromatography was then used as a second cleanup step to maximize the elimination of lipids (~95% of lipids removal). Particular attention was paid to procedural contamination management. Two instrumental methods were developed and optimised in terms of spectrometric and chromatographic conditions by GC-MS/MS operating in positive Electron Impact (EI) or Atmospheric Pressure Chemical Ionization (APCI). The main advantage of 'soft' APCI over 'hard' EI technique was the reduced fragmentation which increases the specificity of transitions in MRM method, especially for the 2 brominated compounds. The perspective of this work will be to evaluate the method performances and hence the reliability of its application.

MO052

Organophosphate Flame Retardants in the Indoor Environment: A Comparison of Central Europe and North America

M. Krátká, . Vojta, Masaryk University / RECETOX Research Centre for Toxic Compounds in the Environment; M. Venier, Indiana University / SPEA; J. Becanova, Masaryk University / RECETOX Research Centre for Toxic Compounds in the Environment; K. Romanak, Indiana University; L. Melymuk, R. Prokes, Masaryk University / RECETOX Research Centre for Toxic Compounds in the Environment; J.O. Okeme, University of Toronto / Physical and Environmental Sciences; A. Saini, University of Toronto / Department of Physical and Environmental Sciences; M.L. Diamond, University of Toronto / Department of Earth Sciences; J. Klanova, Masaryk University / RECETOX Research Centre for Toxic Compounds in the Environment

Flame retardants (FRs) have been used for several decades to prevent fire and reduce the flammability of a wide range of materials. These properties are offset by their environmental persistency, toxicity and bioaccumulative potential. Worldwide restrictions on the use of old types brominated FRs have therefore resulted in the increased use of alternate compounds, such as organophosphate flame retardants (OPFRs), produced in increasing volumes in recent years. Since in most applications OPFRs are used as additive chemicals and therefore are not covalently bound to the polymeric materials, they can be released easily. Due to their presence in common household products, humans are exposed to the released OPFRs in the indoor environment, especially as people spend most of their time indoors. Air, dust and window film samples were collected from a total of 63 houses and apartments in the Czech Republic, Canada and USA during a sampling period of 28 days in May-August 2013. Samples from one room, usually the bedroom, were collected in each home while a second room, usually the living room, was sampled in 10 randomly chosen homes in each country. In addition to the sampling, data about the building and the household were also collected, i.e. information on electronic equipment and furniture in the sampled rooms, occupants, cleaning, ventilation habits, etc. The objectives of the present study were to examine the concentration of 18 OPFRs found in different matrices in the same room and compare individual rooms in the same home, identify possible sources of these compounds in indoor environments and study regional differences in Central Europe and North America. The OPFRs measured in the highest concentrations were tris(2-butoexyethyl)phosphate (TBOEP), tri-n-butylphosphate (TNBP), triisobutylphosphate (TIBP), tris(1-chloro-2-propyl)phosphate (TCIPP) and 2-ethylhexyl diphenyl phosphate (EHDP) in all countries, however the dominant congeners in each matrix differed slightly between North American and Czech samples. For example, 66% of the total OPFR mass in Canadian air samples was TCIPP and 17% was TNBP, while in Czech air samples 53% was TCIPP but the second highest concentration OPFR was TIBP, accounting for 26% of the total mass. The results suggest there are general similarities in the use and composition of OPFRs between Europe and North America, but differences in individual OPFRs which may be indicative of differences in use between the two continents.

MO053

Halogenated Flame Retardants in Spanish air: a human exposure study.

C. Corcellas, IDAEA / Department of Environmental Chemistry; A. Alastuey, M.

Viana, IDAEA CSIC; X. Querol, Institute of Environmental Assessment and Water Research IDAEA-CSIC; E. Eljarrat, IDAEA-CSIC / Department of Environmental Chemistry; D. Barcelo, IIQAB-CSIC / Dept Environmental Chemistry

Dechloranes (Decs) are flame retardants (FRs) which have been one of the most used chemical families as substitutes of banned FRs such as PBDEs. Chemically, dechloranes are chlorinated norbornene structures. This family include dechlorane 602 (Dec 602), dechlorane 603 (Dec 603), dechlorane 604 (Dec 604) and dechlorane plus (DP). Recently, some studies demonstrated the presence of these substances in atmosphere, environment, biota and even food. Other emerging halogenated FRs that are under study in these works are decabromodiphenyl ethane (DBDPE), pentabromoethylbenzene (PBEB) and hexabromobenzene (HBB). Given that some studies point out the potential bioaccumulative character of these FRs, nowadays their chronical toxicity is a hot issue. However, the evaluation of the exposure and ingestion of these compounds is very important in order to evaluate accurately their toxicity. In this context, our aim was to fill the gap of knowledge about Spanish air concentration of these pollutants and compare it with air concentration of banned PBDEs. To do it, we studied 8 different locations all across Spain. Besides, in one of the biggest cities of Spain, Barcelona, we carried out a study along the week in order to describe weekly trends. Finally, we collected samples of indoor environments from Barcelona to compare indoor and outdoor atmospheres. All these samples (49) were analyzed with a GC-MS/MS technique to determine dechloranes. Besides, the same samples were analyzed by GC-MS to determine PBDEs, DBDPE, PBEB and HBB concentrations. Results showed that PBEB, HBB and PBDE-28 were never detected. From Dec family, Dec 604 was never detected in any sample. The most present pollutants were DP and BDE-209. Range of S_8PBDE in outdoor and indoor environments was 0.36-61.0 and 0.84-18.4 pg/m^3, respectively. Moreover, Decs showed a range from 0.25 to 18.3 and from 3.43 to 27.8 pg/m^3 for outdoor and indoor respectively. With this information, we calculated the human exposure to these pollutants by inhalation and dust consumption. The exposure was evaluated as daily intake (DI). DI of PBDE and Decs in outdoors for an adult were estimated as 16.2 and 0.39 pg/day, respectively. In a work place, the DI for an adult was estimated in 32.2 and 59.6 pg/day for PBDE and Dec, respectively.
Acknowledgments - This work has been funded by the Generalitat de Catalunya (Consolidated Research Group Water and Soil Quality Unit 2009-SGR- 965).

MO054

Distribution of organophosphate ester flame retardants between gas and particle phases - model predictions vs. measured data

R. Suehring, University of Toronto; H. Wolschke, Helmholtz Centre Geesthacht; M.L. Diamond, University of Toronto / Department of Earth Sciences; L.M. Jantunen, Environment Canada / Air Quality Processes Research Section Centre for Atmospheric Research Experiments; M. Scheringer, ETH Zurich / Institute for Chemical and Bioengineering

The use of organophosphate esters (OPEs) has increased due to their use as replacements for the restricted polybrominated diphenylethers (PBDEs). That OPEs are a suitable replacement for PBDEs is being debated, especially since recent studies suggest that a number of OPEs have a persistence similar to PBDEs and can be found in remote environments such as the Arctic. The gas-particle partitioning is a key factors to predict where and how chemicals are distributed. The majority of studies measuring OPEs have focussed on the particle- phase, because OPEs have been reported to primarily partition to particles in air. However, considering the variety of physico-chemical properties of OPEs, the expectation that they are mainly in the particle phase "as a class" seems unlikely. To re-assess the hypothesis we compared gas-particle partitioning predictions for 32 OPEs by the commonly used risk assessment tool - OECD P_{OV} and LRTP Screening Tool ("the Tool") – with the partitioning behaviour models of Junge-Pankow and Harner-Bidleman, as well as recently measured data on OPE gas-particle partitioning. The results presented in this study indicated that OPEs with an octanol-air partitioning coefficient (log K_{OA}) below 10 and a subcooled liquid vapour pressure (log P_L) above -5, respectively, partition into the gas-phase rather than the particle phase, regardless of which model was used for prediction. The uncertainty of input data did not change these general observations, even when assuming large uncertainty factors of > 5. The predictions by the Tool as well as the other partitioning models were, furthermore, in good agreement with OPE partitioning measured during a one year stationary sampling by Wolschke et al. (2015). Total suspended particle concentration in air was identified as the factor most influential for the predicted partitioning by the Tool, while the Tool seemed to underestimate the impact of temperature. The generalisation that OPEs as a "class" partition into the particle phase could not be affirmed by the results of this study. Depending on environmental conditions and physico-chemical properties, half of the investigated OPEs were found to primarily partition into the gas phase, as expected from their vapour pressures. Our results emphasise the importance of sampling location and design on measurement results as well as the necessity to assess the risk of OPEs individually, rather than as a homogeneous class.

MO055

Organophosphate esters in the Canadian Arctic - Conclusions from seven years of ship-based observations

R. Suehring, University of Toronto; M.L. Diamond, University of Toronto / Department of Earth Sciences; M. Scheringer, ETH Zurich / Institute for Chemical and Bioengineering; M. Pucko, University of Manitoba; G. Stern, Fisheries and Oceans Canada; L.M. Jantunen, Environment Canada / Air Quality Processes Research Section Centre for Atmospheric Research Experiments

Organophosphate esters (OPEs) have been increasingly used as replacements for the restricted polybrominated diphenylethers (PBDEs) in addition to other uses such as plasticizers. This has led to major increases in environmental levels of OPEs, including the detection in remote environments such as the Arctic where concentrations surpassthose of PBDEs. To assess the behaviour and trends of OPEs concerning long-range transport (LRTP), 14 OPEs were measured in the particle phase of air samples taken during yearly ship-based sampling campaigns from 2007 to 2013 in the Canadian Arctic. In total, 11 out of the 14 OPEs could be detected with highest concentrations and detection frequencies (> 75%) for the chlorinated OPEs TCiPP, TCEP and TDCPP as well as the non-chlorinated OPE TPhP. All other OPEs were detected in 20 % or less of the analysed samples. Median concentrations ranged from 1.0 pg/m^3 (TCP2) to 152 pg/m^3 (TCEP). Interestingly, high concentrations of up to 2300 pg/m^3 were observed for TnBP at a stationary sampling location in Resolute Bay from 2012, while this compound could not be detected in any of the ship-based samples. PIA (version 13) program was used to analyse trends in time-series datasets. We observed general increasing temporal trends from 2010 to 2014 for total OPEs. This was driven by an overall increase of non-halogenated OPEs, while halogenated OPEs seemed to be stable or slightly decreasing. Overall, concentrations of halogenated OPEs seemed to be primarily location and temperature dependent with river discharge from the Nelson and Churchill Rivers (MB) as well as Lake Melville (NF) as sources. In contrast, non-halogenated OPEs seemed to be driven by diffuse sources. The results of this study further emphasise the increasing relevance of halogenated as well as non-halogenated OPEs as contaminants in the Arctic and provides unique information on trends, transportation behaviour and pathways of OPEs into this remote environment.

MO056

Diastereomer profiles of Hexabromocyclododecane in global air samples from the Global Atmospheric Passive Sampling (GAPS) Network

C. Rauert, Environment Canada / Air Quality Processes Research Section; J. Schuster; M.E. Shoeib, Environment Canada / Atmospheric Science and Technology Directorate; T. Harner, Environment Canada / Atmospheric Science Technology Directorate

Hexabromocyclododecane (HBCD) is a globally used brominated flame retardant (BFR), added to Annex A of the United Nations Environment Program (UNEP) Stockholm Convention for Persistent Organic Pollutants (POPs) in 2013. It is a priority chemical for monitoring under Canada's Chemicals Management Plan (CMP) and the Convention's global monitoring plan (GMP). The majority of outdoor air studies have analysed total HBCD content using gas chromatorgarphy mass spectrometry (GC-MS). However determining the contribution of the three main diastereomers present in the HBCD technical formulation, and the three primarily found in the environment: α-, β- and γ-HBCD, may provide insight to the emission sources, transformation and atmospheric transport of the HBCD diastereomers. The present study has developed a sensitive and selective method for the determination of α-, β- and γ-HBCD in outdoor air samples utilising Ultra Performance Liquid Chromatography tandem Mass Spectrometry (UPLC-MS/MS). Polyurethane foam (PUF) disk passive air samples (PAS) from the Global Atmospheric Passive Sampling (GAPS) network, deployed in 2009 and 2014, were analysed with the developed method to provide an indicator of global outdoor air concentrations of HBCD and the relative diastereomer contributions in air. Detection frequency was low, owing to the reduced concentrations of HBCD in outdoor air as compared to indoor air, with HBCD detected in ~20% of the samples and concentrations ranged from < LOD to 7.0 pg/m^3 (∑HBCD).
Acknowledgement - The authors thank the Chemicals Management Plan (CMP), the United Nations Environment Program (UNEP) and the Northern Contaminants Program (NCP) for funding and support.

MO057

Presence and distribution of 39 emerging flame retardants in a secondary wastewater treatment system

J. Cosgrove, AXYS; M. Woudneh, AXYS Analytical Services Ltd / RD Chemist; C. Hamilton, Axys Analytical Services Ltd. / Client Services; R.D. Grace, AXYS Analytical Services Ltd

In this study, an analytical method was developed for analysis of 39 emerging flame retardants (FRs) using a dual instrument platform (LC-MS/MS and GC-(ECNI)MS). Target compounds included: 13 organophosphorous FRs, 7 dechloranes and related FRs, five tribromophenyl ether FRs, 12 monoaromatic FRs and degradation products. The method involved liquid-liquid extraction for aqueous samples and soxhlet extraction for solid and biosolid samples. Extracts for the LC-MS/MS analysis were cleaned up using silica gel and NH2 SPE cartridges. Extracts for the GC-(ECNI)MS were cleaned up using liquid-liquid cleanup with aqueous acetonitrile at three pHs followed by gel permeation cleanup. The methods were validated for accuracy, precision, matrix effects, analyte adsorption as well as sample and extract stability. The developed method was applied to investigate the occurrence and distribution of these flame retardants both in the liquid and solid waste streams of a typical secondary wastewater treatment system employing activated sludge treatment. The method's performance in this study demonstrated its applicability for monitoring these emerging contaminants in the environment.

MO058

Indoor Sources of Tris(chloropropyl) phosphate (TCPP) and Concentrations Outdoors in Tributaries, Rain, and Wastewater Treatment Plant Effluent

J. Truong, University of Toronto / Chemical Engineering and Applied Chemistry; L.M. Jantunen, Environment Canada / Air Quality Processes Research Section; P.A. Helm, Ontario Ministry of the Environment & Climate Change / Environmental Monitoring and Reporting Branch; G.M. Webster, Simon Fraser University / Faculty of Health Sciences; P. Kurt-Karakus, Bursa Technical University / Environmental Engineering Department; M.L. Diamond, University of Toronto / Department of Earth Sciences

Organophosphate esters (OPE's) are commonly used as plasticizers, lubricants and as flame retardants. OPEs are a concern because of recent reports of high concentrations indoors, in surface waters, herring gull eggs and fish, and their potential toxicity to aquatic biota and humans. Since OPEs are typically employed as additives that are not chemically bonded, they are released from products into the environment via volatilization, dissolution and abrasion. Here we first investigated one indoor source of an OPE and second, documented tris(chloroisopropyl) phosphate (TCPP) concentrations in multiple outdoor media. The indoor source of TCPP to indoor air and dust was linked to spray polyurethane foam (SPF) insulation in a highly insulated home using the isomeric fingerprint signature of TCPP. High levels of TCPP were measured in the highly insulated house in dust (85 ± 47 ug/g) and air (23 ± 8.4 ng/m^3). The isomeric fingerprint of TCPP 1:2 (first and second eluting isomers) were statistically indistinguishable from the SPF insulation used (4.0 ± 0.2, vs 4.1 ± 0.1), whereas the ratios differed significantly from other environmental samples (ANOVA, $p < 0.05$). This evidence suggested that the SPF was the source of TCPP to the highly insulated home. In comparison, the ratio of TCPP 1:2 was 3.2 ± 0.9 in dust from homes in Vancouver Canada and 3.9 ± 0.5 in Istanbul, Turkey. Second, we documented concentrations of TCPP in three Toronto tributaries during high and low flow periods, in the final effluent from three wastewater treatment plants (WWTP), and in bulk rain water. TCPP in WWTPs had the highest average concentrations, followed by tributaries during high flow periods, and tributaries during low flow periods (ANOVA, $p < 0.05$). TCPP in WWTP final effluent was of 6.6 ± 11 µg/L (0.054 -18 µg/L). Tributaries differed from each other only during high versus low flow periods and not from each other, with TCPP concentrations averaging 4.2 ± 3.9 µg/L (0.22-11 µg/L) and 0.86 ± 0.95 µg/L (0.11-6.8 µg/L), respectively. TCPP concentrations in tributaries correlated with water discharge (m3/s), with a Pearson Correlation Coefficient of 0.65. No correlations were evident between TCPP concentrations and suspended solids or turbidity in tributary water, unlike PBDEs. Tributary concentrations of TCPP correlate with other OPEs analyzed in these water, notably TCEP (r= 0.89) and TCDPP (r=0.88).

MO059

Evaluation of sediment contamination by historical POPs and alternative flame retardants in the Gironde estuary

M. Lauzent, LPTC-EPOC, University of Bordeaux / UMR EPOC LPTC; K. Le Menach, H. Budzinski, University of Bordeaux / UMR EPOC LPTC; P. Labadie, CNRS

Human activities exert different types of pressure on ecosystems, including the chemical pressure associated with the release of numerous synthetic organic compounds such as halogenated organics. A number of these chemicals may be persistent, such as polychlorinated biphenyls (PCBs) and polybrominated biphenyls ethers (PBDEs) which were officially classified as persistent organic pollutants (POPs) and are subject to regulations and restrictions. To address these limitations of use, alternative flame retardants (FRs) have been and are increasingly used. A comparison was performed on sediments from the Gironde estuary, between the levels of legacy POPs (PBDEs, PCBs and organochlorine pesticides (OCPs)) and those of emerging FRs: 11 brominated, 7 phosphorus and 6 chlorinated alternative flame retardants including (bis(2-ethyl-1hexyl)tetrabromophthalate (BEHTBP), 2-ethylhexyl 2,3,4,5-tetrabromobenzoate (EHTBB), pentabromotoluene (PBT), tetrabromoethylcyclohexane (abTBECH), octabromotrimethylphenyllindane (OBIND), pentabromoethylbenzene (PBEB), 1,2-bis(2,4,6-tribromophenoxy)ethane (BTBPE), decabromodiphenylethane (DBDPE), hexachlorocyclopentenyl-dibromocyclooctane (HCBDCO), hexabromobenzene (HBB), 2,3-dibromopropyl-2,4,6-tribromophenyl ether (DPTE), tris(2-chloroethyl) phosphate (TCEP), tris(chloropropyl)phosphate (TCPP), 1,3-Dichloro-2-propanol phosphate (TDCPP), Triphenyl phosphate (TPhP), Tricresyl phosphate (TCP), Diphenylcresylphosphate (DCP), Tri-n-butylphosphate (TnBP), Dechlorane Plus (anti, syn), dechlorinated DP products (aCl10DP and aCl11DP), dechloranes (Dec-602 and Dec-603)). Sampling was conducted in September 2014, on 23 points in the subtidal zone and 13 points in the intertidal zone, from the confluence of the Dordogne and the Garonne River to the river mouth at the Pointe du Verdon. This work provides a first mapping of the contamination of the Gironde estuary by legacy POPs and alternative FRs. Controlling factors of POPs/alternative FRs will also be discussed. *Acknowledgements* - The data come from the HALOGIR campaign carried out on the research vessel Côtes de la Manche CNRS-INSU. This study has been carried out in the frame of the Investments for the future Programme, within the Cluster of Excellence COTE (ANR-10-LABX-45). Aquitaine region is acknowledged for PhD grant funding. CPER A2E (Aquitaine region and FEDER) is acknowledged for financial support for instrument acquisition.

MO060

Halogenated flame retardants in eggs of Spanish birds

. Aznar-Alemany, Dept of Environmental Chemistry; M. MallÃn, IDAEA-CSIC / Dept of Environmental Chemistry; G. Blanco, MNCN-CSIC / Dept of Evolutionary Ecology; E. Eljarrat, IDAEA-CSIC / Department of Environmental Chemistry; D. BarcelB, ICRA

Flame retardants (FRs) are compounds applied to materials to increase their fire resistance. Polybromodiphenyl ethers (PBDEs) are the most used FRs and can be found in plastics, furniture or electronic devices. They are classified according to their level of bromination. Since PBDEs are not bonded into plastics but blended, they can leach out and are found in different environmental matrices. PBDEs are persistent and toxic, bioaccumulate and suffer long-range transport. They are considered persistent organic pollutants in the Stockholm Convention and their production has been banned in Europe and North America. Hence new brominated FRs, are used as substitutes; as well as chlorinated FRs, including halogenated norbornenesЙ_or dechloranes. The present study investigates the occurrence of halogenated FRs in unhatched eggs of 7 bird species from central Spain as well as liver tissue from deceased individuals. Samples include 30 eggs and 11 livers from years 2009-2015. The analytical method monitored 8 PBDEs, 3 emerging brominated FRs (DBDPE, HBB and PBEB) and 5 dechloranes (*syn*- and *anti*-Dechlorane Plus and Decs 602, 603 and 604). For the sample preparation lyophilized sample was spiked with internal standards, extracted by PLE, cleaned and purified by an acidic attack and SPE. Extracts were analysed by GC-MS/MS. Method recoveries for the compounds ranged 51-88 %. Method LODs and LOQs were 0.01-3.2 ng/g lipid weight (lw) and 0.03-10.8 ng/g lw. PBDEs were detected in all samples, with total concentrations below 319 ng/g lw, except for one sampling spot where they reached 4,292 ng/g lw. BDE-47, -99 and -100, which correspond to the PentaBDE commercial mixture, were the main contributors to the profiles. Dechlorane levels were in the same order of magnitude as PBDE levels in all the spots. Even without taking the most polluted spot into account, the rest of the results are still higher than those found in Doñana Natural Park (south of Spain), maybe because the latter is better protected [1]. *Acknowledgments* – This work has been funded by the Generalitat de Catalunya (Consolidated Research Group Water and Soil Quality Unit 2009-SGR- 965). MO061

Occurrence of polybrominated diphenyl ethers and emerging halogenated flame retardants in food items

G. Poma, University of Antwerp, Toxicological Center / Toxicological Center; N. Symons, G. Malarvannan, University of Antwerp Toxicological Center; S. Goscinny, Scientific Institute of Public Health Belgium; S. Voorspoels, Flemish Institute for Technological Research VITO NV; S.V. Malysheva, J. Van Loco, Scientific Institute of Public Health Belgium; A. Covaci, University of Antwerp, Toxicological Center / Toxicological Center Dept of Pharmaceutical Sciences

Brominated flame retardants (BFRs) are chemicals used in a wide range of commercial and household products in order to reduce their flammability. Because most BFRs are not chemically bonded to the products which they are added to, they can easily leach into the environment. People are mainly exposed to BFRs via dust and diet. In particular, the lack of data on the occurrence of BFRs in food prevents an accurate estimation of the human intake. The main aim of this project was to follow up the European Commission Recommendation 2014/118/EU on the monitoring of BFRs in various food items on the Belgian market and to provide data on their occurrence and levels in the main food categories. The presence of polybrominated diphenyl ethers (PBDEs), novel BFRs (hexabromobenzene (HBB), bis(tribromophenoxy)ethane (BTBPE), tetrabromobenzoate (TBB), tetrabromophthalate (TBPH)), tribromoanisole (TBA), and dechlorane plus (syn-DP and anti-DP) in various food items was assessed using an analytical method developed and validated in this project. This novel method uses low sample amounts and solvent volumes, and involves a two-step clean-up, including florisil and acid silica. The determination of BFRs was performed using gas chromatography-mass spectrometry operated in electron-capture negative ionization mode (GC-ECNI/MS). The validated procedure was first used for the determination of BFRs in 20 individual food items purchased from Antwerp supermarkets (including fish, meat, chicken eggs, cow milk, grains and vegetable oil), and, in a second stage, has been used for the analysis of more than 200 food samples in the frame of the Belgian food monitoring project. A high extraction performance was obtained, which, in combination with an efficient two-step clean-up procedure, enabled the accurate determination and quantification of the target compounds in a wide variety of food matrices, with different characteristics and lipid content. In all food categories, PBDEs were the most frequently detected and were predominant in fish/seafood samples. Among other FRs, TBA was detected only in fish/seafood, indicating its primary natural origin from the marine environment. For the other compounds, the results showed a generally low contamination of all analyzed food samples, with values generally below the quantitation limit (LOQ).

MO062

Brominated flame retardants in Belgian foodstuffs - recent evaluation by a novel UPLC-MS/MS method

S. Malysheva; S. Goscinny, Scientific Institute of Public Health Belgium; G. Malarvannan, University of Antwerp / Toxicological Center Dept of Pharmaceutical Sciences; G. Poma, University of Antwerp, Toxicological Center / Toxicological Center; M. Andjelkovic, Institute of Public Health; S. Voorspoels, Flemish Institute for Technological Research VITO NV; A. Covaci, University of Antwerp, Toxicological Center / Toxicological Center Dept of Pharmaceutical Sciences; J. Van Loco, Scientific Institute of Public Health Belgium

The study was undertaken as consequence of the Commission Recommendation 2014/118/EU on the Europe-wide monitoring of brominated flame retardants (BFRs) in food. BFRs are anthropogenic chemicals that are added to a wide variety of consumer products in order to improve their fire resistance. BFRs may leach from the products into the environment. Due to their persistence and potential to bioaccumulate in the food chain, BFRs may cause toxic effects in humans and animals. There is a lack of information on the occurrence of BFRs in foodstuffs, which has hampered accurate completion of intake assessments. The main objective of this work was to evaluate the presence and to measure the levels of BFRs, namely brominated phenols (BPs), hexabromocyclododecanes (HBCDs), tetrabromobisphenol A (TBBPA) and its derivatives in foodstuffs consumed by the Belgian population. Quantitative measurements were performed using ultra-high performance – tandem mass spectrometry (UPLC-MS/MS) on an ACQUITY UPLC system coupled to a Xevo-TQ-S mass spectrometer. Sample preparation protocol consisted of a QuEChERS-based extraction followed by two parallel clean-up procedures. Column chromatography with acidified silica gel and dispersive solid-phase extraction with C18 and carbon sorbents were used to eliminate lipids, pigments and eventually other matrix components from the extract. The method is applicable to a wide variety of food matrices and was in-house validated. Representative portions of food samples belonging to different categories, such as fish and seafood, meat and meat products, chicken eggs, oils and fats, milk and dairy products, were collected from Belgian (super)markets in 2015. The samples were pooled per food category according to the consumption data of the Belgian Food Consumption Survey, after which they were lyophilized and subjected to the multi-analyte LC-MS/MS analysis. In this work, data on the occurrence and levels of BFRs in different food commodities consumed in Belgium will be presented. The results will be discussed with regards to the frequency of occurrence and highest detected concentrations of the BFRs, and compared to existent data for other (European) countries. This data will be decisive in the subsequent calculation of intake levels. *Acknowledgments*: Financial support from Federal Public Service (FPS) Health, Food Chain Safety and Environment

MO063

Gas chromatography/atmospheric pressure chemical ionisation/tandem mass spectrometry to perform non-polar brominated flame retardants monitoring in food items at ppt levels

E. Bichon, I. Guiffard, P. Marchand, LUNAM Université / Oniris Laboratoire dÉtude des Résidus et Contaminants dans les Aliments; B. Le Bizec, Oniris-LABERCA / Oniris Laboratoire dÉtude des Résidus et Contaminants dans les Aliments

Brominated Flame Retardants (BFRs) have been analysed in food items for a decade in France to establish the French food exposure. The analytical methodology was first focused on Polybrominated diphenyl ethers (PBDEs) often implying a double injection on a gas chromatograph coupled to a high resolution mass spectrometer in electromagnetic field to detect the low and high m/z separately in HRSIM, i.e. from tri- to hepta-BDE in the first injection and deca-BDE in the second one. Since some PBDEs products have been replaced by novel or emerging BFRs, the list of compounds of concern in food is still increasing continuously (118/2014/EU recommendation), adding one or two more injections of the same extract in GC/HRMS and increasing the analysis time and the cost of each analysis dramatically. Nowadays, analytical alternatives are envisaged such as gas chromatography coupled with tandem mass spectrometry using atmospheric pressure chemical ionization (GC/APCI/MS/MS), which allow a higher throughput analysis. The aim of our work was to propose a methodology to monitor PBDEs and 12 additional BFRs under "routine conditions", i.e. a single injection of the extract conducted in a short acquisition time under robust conditions. The interface parameters were first optimized and the APCI+ ionization under dry mode was chosen with a 2 μA corona current. Then, MS/MS events were mainly performed on the molecular ion, giving a high specificity to the signal. The quality of BFRs introduction in the mass spectrometer being the most critical point, the inlet conditions were completely reviewed. The chromatographic system was optimized in working on the fundamentals, i.e. injector and liner qualities, columns geometries and associated velocities and gradient of temperature (always on 5MS stationary phase type). A compromise was established on the basis of the optimal HETP and resolution calculation and on the DecaBDE degradation to maintain at the same time the integrity of heaviest BFRs and chromatographic efficacy and resolution for the other ones. The final methodology was implemented on the national control plan samples and illustrations will be given during the SETAC conference to describe? the robustness of the GC/APCI/MS/MS method and its applicability for routine analysis at ppt level in food.

MO064

In vitro bioaccessibility of plasticisers present in indoor dust using simulated human lung fluids

K. Kademoglou, University of Reading / geography and Environmental Sciences; G. Giovanoulis, IVL Swedish Environmental Research Institute Ltd / IVL Swedish Environmental Institute; J.A. Magnér, IVL Swedish Environmetal Research Institute Ltd / IVL Swedish Environmental Institute; C.D. Collins, Reading University / Soil Research Centre; C.A. de Wit, Stockholm University / Department of Environmental Science and Analytical Chemistry ACES

Plasticizers are additives imparting durability, elasticity and flexibility in the manufacture of polymeric products such as PVC flooring, retailing and packaging materials. The lack of migration stability has resulted into their classification as major indoor contaminants. Despite their extensive everyday use, the process of assessing human exposure and possible health effects arising from indoor air contamination only began the past decade with limited results so far. This study forms a part of the EU Marie Curie Initial Training Network "Advanced Tools for Exposure Assessment and Biomonitoring" (A-TEAM) aiming to develop and establish novel methods on human exposure biomonitoring of pseudo-POPs including phthalate esters (PEs) and alternative plasticisers, having as a study group indoor dust originating from N=61 participants' houses in Norway. In the present study, we investigate the *in vitro* bioaccessibility (i.e. uptake/absorption) of plasticisers present in indoor dust collected from vacuum cleaner bags with respect to potential routes of exposure including inhalation and respiration. Simulated artificial human body fluids are used regarding the relevant exposure route, i.e. lung fluids. Indoor dust is sieved at 63 µm using an methanol-washed metallic sieve. 200 mg of sieved dust samples are incubated with 20 mL of artificial lung fluid (ALF) at 37ºC for the artificial lung fluid in order to set up a realistic exposure scenario. All media incubations are conducted continuously for 96h. After the incubation step has finished, the samples are centrifuged at 3000rpm for 10min and the supernatant is subjected for a liquid-liquid extraction (LLE) using MTBE:Hexane 3:1. A selective and sensitive method to determine the analytes of interest is employed by using triple quadrupole gas chromatography mass spectrometry (GC-MS/MS) in multiple reaction monitoring (MRM) mode. The method validation was performed using Standard Reference Material for indoor house dust (i.e. SRM 2585) in replicate analysis and the results show that low molecular weight phthalates (e.g. DMP & DEP) are more than 85% bioaccessible through the simulated lung fluids, while the high molecular weight phthalates and alternative plastisisers (e.g. DEHP and DEHT) presented bioaccessibility values less than 5%.

MO065

Are some "safer alternatives" of Flame Retardants hazardous as PBTs? Screening of FRs by the cumulative PBT Index in QSARINS

A. Sangion, P. Gramatica, S. Cassani, University of Insubria / DiSTA

Flame Retardants (FR) are chemicals widely used to enhance fire safety of industrial and commercial products. However chemicals like PBDE, largely used in the past, demonstrated to have unintended negative effects to human health and wildlife due to their properties of Persistence, Bioaccumulation and Toxicity (PBT). Nowadays such chemicals are replaced by New FRs (NFRs), as New Brominated FRs (NBFRs) and Halogen Free FRs (HFFRs) or Organophosphorous FRs (OPFRs) supposed to be "safer alternatives". Nevertheless, the information about the chemical properties of these substitutes are often not available and these substances were commercialized without complete information regarding their PBT properties, that are based on long-term behaviors and would require complex and expensive experiments. However, the PBT assessment is expressly required in the context of REACH regulation and PBT chemicals require an authorization. In recent years many monitoring studies have identified these alternative FRs in various environmental compartments and in wildlife. In this study, several new compounds, proposed and used as "safer alternatives" to PBDEs, were analyzed with multivariate evaluation tools and screened with the cumulative PBT Index, a MLR QSAR model that allows to identify PBT chemicals directly from their molecular structure, implemented in QSARINS (QSAR INSubria) software. A rigorous check of the chemicals that are included in the model Applicability Domain (AD), and for this reason with the most reliable predictions, has been done. The results, obtained directly from the chemical structure for the three properties altogether, have been compared with those obtained by the US-EPA PBT Profiler and a good agreement (73%) between the two different approaches was found, resulting in a more precautionary assignment of PBT Index. A priority list of the potentially most hazardous FRs, predicted by consensus from both the approaches, has been proposed, highlighting that some compounds, proposed and already used in commerce as supposed safer alternatives, are identified as intrinsically hazardous for their PBT properties, explaining why they are detected all over the world. This study also shows that stuctural modeling approaches, such as PBT Index, could be valid tools to evaluate appropriate and safer substitutes, *a priori* from the chemical design, in a benign by design approach, avoiding unnecessary synthesis and expensive experimental tests.

MO066

Identification of species differences in the effects of androgenic compounds using in silico and in vitro methods

S. Asnake, A. Pradhan, J. Kharlyngdoh, C. Modig, P. Ivarsson, P. Olsson, Orebro University / The Life Science Center

Endocrine disrupting chemicals (EDCs) are compounds that cause reproductive and developmental disturbances. Brominated flame-retardants (BFRs) are one group of EDCs that have been shown to affect the normal function of endocrine, behavioural, reproductive, metabolic and neurological systems. BFRs are used extensively in commercial and industrial appliances to meet fire safety regulations and reduce the flammability of materials. Because of their low cost and high efficiency the use of BFRs has increased rapidly. These, in turn have resulted in an increased release to the environment and these have been detected in avian, aquatic and mammalian species. In this study we included two groups of BFRs, TBECH diastereomers (α, β, γ and δ) and derivatives of 2,4,6, tribromophenol (TBP), allyl 2,4,6-tribromophenyl ether (ATE), 2-bromoallyl 2,4,6-tribromophenyl ether (BATE) and 2,3-dibromopropyl 2,4,6-tribromophenyl ether (DPTE) that were studied for their effects on androgen receptor (AR) functioning. To investigate whether the TBECH diastereomers and TBP derivatives bind to the androgen receptors of the chicken, zebrafish and human an *in silico* molecular docking and dynamics procedure was performed by using the MOE and ICM modelling software. These showed that both sets of BFRs can bind to the ARs in the different species. To confirm the *in silico* results, *in vitro* activation assay studies by using chicken LMH, zebrafish ZFL and human HepG2 cells were performed. This demonstrated that the TBECH diastereomers acted as agonists and the TBP derivatives acted as antagonists to the ARs. It also showed that TBECH diastereomers are strong inducers of the human AR followed by the zebrafish and chicken ARs. This reveals that because of the sequence difference between the species the same compound can function differently. The TBP derivatives set acted as strong antagonists with comparable potencies between the species. In conclusion, the majority of chemicals that are being used in products have still not been tested and their effects on the endocrine system have therefore not been studied. The rapid identification of compounds that can disrupt the normal functioning of the endocrine system is crucial and this study demonstrates that the use of *in silico* and *in vitro* techniques can be used as a fast and reliable method of identifying compounds with unknown biological properties.

MO067

Applying the RAIDAR model for ecological risk assessment: A case study for 10 organic flame retardants.

J.A. Arnot, ARC Arnot Research & Consulting / Department of Physical Environmental Science; A. Falls, ARC Arnot Research & Consulting; J.M. Armitage, University of Toronto - Scarborough / Physical and Environmental Sciences; T. Gouin, Unilever / Safety and Environmental Assurance Centre; L. Toose, ARC Arnot Research and Consulting; M.A. Bonnell, Environment and Climate Change Canada / Ecological Assessment Division

Chemicals are being evaluated to determine if they pose unacceptable risks to humans or the environment. Measured (monitored) concentrations in environmental media are non-existent or limited for the vast majority of chemicals produced and used by society. The extensive exposure data gaps hinder the application of risk-based methods for chemical prioritization, screening and comprehensive assessments. The chemical activity approach has been proposed as an integrating concept for chemical risk assessment. The Risk Assessment Identification And Ranking (RAIDAR) model includes multimedia mass balance fate calculations for organic chemicals in air, water, soil, sediment and representative aquatic and terrestrial species and food web bioaccumulation models comprising various trophic levels (e.g., plants, invertebrates, fish, birds and mammals). Here we conduct a case study for screening-level ecological risk assessment using measured and estimated exposure and toxicity data and the RAIDAR model for 10 organic flame retardants (OFRs). The 10 OFRs include chlorinated, brominated and organophosphate flame retardants. The chemicals cover a diverse range of chemical properties for partitioning, reaction, persistence, bioaccumulation and toxicity. A database of 3,120 measured concentrations of 10 OFRs in temperate North America is used to derive emission rate estimates using inverse modelling and to evaluate the model calculations. Estimates of risk are quantified by comparing exposures and effects expressed in terms of chemical activity. Uncertainty in model input parameters (partitioning properties, degradation half-lives, emission rate estimates and toxicity) is used to estimate uncertainty in the RAIDAR risk calculations. A comparative risk assessment is used to rank the OFRs for their relative risks to the environment based on current information for toxicity and chemical emission rates. Comparable risks of OFRs in the environment are partially explained by an inverse relationship between chemical emission rates and overall persistence.

MO068

Toxicity Profiling Of Flame Retardants In Zebrafish Embryos Using A Battery Of Assays

C. Quevedo, A. Alzualde, A. Alday, BBD BioPhenix-Biobide; M. Behl, R. Tice, R. Paules, NIEHS-NIH; A. Muriana, BBD BioPhenix-Biobide / RD

The developing zebrafish embryo is increasingly used as an alternative animal model for evaluating toxicities. The aim of this study was to assess the toxicity of 10 flame retardants (FRs) of environmental concern using a battery of zebrafish toxicity assays. With the phasing out of brominated FRs (BFR), organophosphate FRs (OPFRs) are increasingly being used. However, there is limited information on their potential for inducing adverse health effects. In this blinded study, 2 BFRs and 8 OPFRs (6 non-halogenated, 2 halogenated) were tested for developmental toxicity, cardiotoxicity, behavioral alterations, and hepatotoxicity. A bioavailability study was conducted to measure the internal compound exposure by LC/MS/MS. To determine the risk of teratogenicity of the tested compounds, the presence of morphological and functional alterations were analyzed and a teratogenic index (TI) established as the ratio of the LC50/EC50. High TI values were obtained for 3 compounds - isopropylated triphenyl phosphate (IPP), tert-butylphenyl diphenyl phosphate (BPDP), and tricresyl phosphate (TCP) (EC50 ~2-5 μM), - that highlight the possible teratogenic potential of these compounds. In terms of cardiotoxicity, 4 of the 6 non-halogenated OPFRs tested (IPP at 100 μM, BPDP from 10 μM, TCP from 30 μM, and triphenyl phosphate from 10 μM) induced bradycardia followed by auricular failure, a specific and uncommon zebrafish cardiotoxic effect. 2,2'4,4'-tetrabromodiphenyl ether (BDE-47) specifically affected locomotor activity from 1 μM, concentration at which not other deficits were observed. Finally, hepatotoxicity was found after the treatment with 2-ethylhexyl diphenyl phosphate (EHDP) and BPDP, for both at 10 μM. In conclusion, the OPFR results support the need for more extensive testing and demonstrate the applicability of this battery of zebrafish assays. This abstract does not necessarily reflect the views of NTP/NIEHS.

Microplastics in the environment: Sources, Fate and Effects (P)

MO069

Comparison of different procedures for quantifying microplastic particles in freshwater samples

J.P. Girardi, German Institute of Hydrology; C. Kochleus, S. Hatzky, C. Theisen, Federal Institute of Hydrology; G. Reifferscheid, Federal Institute of Hydrology / Department Biochemistry and Ecotoxicology; N. Brennholt, Federal Institute of Hydrology / Biochemistry and Ecotoxicology

(Micro)Plastics litter is one of the main environmental issues of the 21st century. While marine litter has been recognized by politics (e.g. through MSFD) and society as an important problem requiring the need for action, the knowledge regarding its origins is still limited. There is for example no information on the amount of litter being transported through rivers into marine habitats. Research institutes as well as authorities have recently started to quantify riverine (micro)plastic litter, but this is being done with a range of different methodologies and approaches. On this account no comparative studies or comparable assessments can be conducted. This project aims at comparing and evaluating five different approaches for quantifying microplastic particles in freshwater samples. Water samples from the river Rhine, Germany, were taken using an Apstein plankton net (150 μm mesh size). Water is eliminated via filtration with membrane glass fiber filters, lyophilisation or centrifugation in three of five procedures. Afterwards, there is an enzymatic digestion of organic compounds using cellulase (E.C. 3.2.1.4), chitinase (E.C. 3.2.1.14) and lipase (E.C. 3.1.1.3) in the first step, followed by addition of protease (E.C. unknown) after some incubation time. In the end a density separation using sodium chloride is performed. The fourth procedure does not feature removal of water before the enzymatic digestion. The last procedure begins with a density separation and filtration ahead of the digestion. Recovery experiments are done using four different kinds of colored plastics: polypropylene (PP), polystyrene (PS), high-density polyethylene (PE-HD) and low-density polyethylene (PE-LD). The particles were categorized into three groups of 200 μm – 630 μm (30 particles of each material), 630 μm – 2000 μm (20 particles) and 2000 μm – 4000 μm (3 particles). After going through the different procedures the remaining particles were counted using a digital microscope. First results of our current research indicate that the recovery and feasibility of the procedure employing water removal via freeze-drying is most successful. A gravimetric comparison concerning the effectivity of the enzymatic digestion of the filtered and freeze-dried sample is ongoing and therefore further results will be presented at the conference.

MO070

Canada's regulatory approach for microbeads

Y. Sultan; S. Cowell, N. Khera, Environment Canada
Microbeads are released into the environment from a variety of applications, including consumer and industrial products. To evaluate the potential environmental impacts of microbeads, the Government of Canada in 2015 completed a science summary, which involved the review of >130 relevant publications and reports. Based on the findings from the review, it was recommended that microbeads be added to the list of toxic substances under the Canadian Environmental Protection, 1999. In addition, a mandatory information gathering survey was published for microbeads to gather sector specific data along with a notice of intent to develop regulations for microbeads. This presentation will highlight key findings from the science summary.

MO071
Fate and impact of model microplastics in freshwater
H. Kong, University of Geneva; S. Stoll, University of Geneva / Institute Forel Earth and Environmental Sciences; C. Hassler, University of Geneva; V. Slaveykova, University of Geneva / Section of Earth and Environmental Sciences Institute Forel
Plastics, originating from voluntary or involuntary release, are considered as an emerging contaminants of global importance and rise concerns about their environmental implication. Although the environmental impact of macroplastic waste is extensively studied, the behavior and the effects of micro-plastics, either unintentionally released in the environment, either formed as a degradation product of the macroplastics is still largely unknown. Owning to their small sizes, microplastics can be readily ingested by the aquatic microorganisms, affect them and accumulate in the aquatic food chain. The present study therefore explores the fate of microplastics in surface water and their effect to water flea *Daphnia magna*. The stability of two model plastic nanoparticles with similar primary size of 200 nm and different surface functionalization, amidine- and carboxyl- group functionalized latex beads, were characterized following their hydrodynamic size and surface charge variations in lake and river water, and *D. magna* test medium. Furthermore the effect on *D. magna* was quantified by using 48h exposure immobilization test and following the uptake in the gut by microscopic observations. Negatively charged carboxyl-latex beads were stable in all tested media as revealed by the unchanged negative z-potential and lack of agglomeration. Interestingly the behavior of the amidine-latex beads was strongly affected by the exposure medium conditions characterized by strong agglomeration in lake and river water, however were stable in *D. magna* exposure medium. Both the positively and negatively charged latex particles were consumed by zooplankton. The amount of the microplastic particles detected in the *D. magna* gut increase with their concentration in the exposure media. The 48h-immobilization tests demonstrated toxicity both micro-plastic particles to the water flea. The EC_{50} of 50 mg/L and 80 mg/L for amidine- and carboxyl- latex beads, respectively were found demonstrating that these microplastics can be considered as harmful for *D. magna*. Overall the obtained results demonstrated the potential of the microplastics to affect aquatic biota, as well as the importance of the particle surface charge in particle-biota interactions and in their reactivity and stability in the aquatic systems.

MO072
The fate of microplastics ingested by Antarctic krill (Euphausia superba)
A. Dawson, Griffith University; S. Kawaguchi, R. King, Australian Antarctic Division / Australian Government Department of the Environment; C.K. King, Australian Antarctic Division; K. Townsend, University of Queensland / School of Biological Sciences; S.M. Bengtson Nash, Griffith University / Southern Ocean Persistent Organic Pollutants Program
Plastics particles less than 5mm (microplastics) are generally accepted to be ubiquitous within the marine environment. With the concentrations of marine microplastics increasing worldwide and reaching the most remote ecosystems, it has become necessary to develop a greater understand of how marine species interact with this relatively recent addition to the marine environment. Antarctic krill are a key species in the Antarctic ecosystem. They are undoubtedly one of the most important organisms in the southern ocean as almost all species residing in the Antarctic depend on krill either directly or indirectly. They also exhibit great dietary flexibility which may leave them vulnerable to the adverse effects of plastic ingestion, including false satiation, leaching of chemical additives and reduced body condition. In order to determine the capacity of Antarctic krill to ingest microplastics and the fate of ingested particles, krill were fed a diet of microplastics and algae with a range of concentrations. The diet consisted of 10, 20, 40 and 80% plastic per dry weight of algae, which ranged from approximately 14.5 to 116.2 plastics mL^{-1}. The model microplastics were fluorescent polyethylene beads with a size range of 27-32 μm and density of 1.026g/cm^3. Krill were kept in 24hr darkness in 0°C filtered seawater for ten days. Feeding occurred daily for four hours and water changes occurred before and after feeding. Faecal pellets were found to contain whole beads and small fragments of plastics, indicating that the mechanical forces of the gastric mill were able to triturate microplastics particles. To investigate this finding further, histological analysis was performed on the digestive tract and on whole krill. The findings are outlined in this presentation.

MO073
Occurrence of microplastics in the stomach content of red mullet (Mullus barbatus) from the Western Mediterranean
C. Martinez-Gomez, A. Martinez camara, V.M. Leon, Instituto Español de Oceanografia / Marine Contamination and Biological Effects; D. Vethaak, DELTARES / Marine and Coastal systems
In this study the occurrence of microplastics (MPs) (< 5 mm – 300 μm) in the stomach content of red mullet (*Mullus barbatus*) from three areas along the Spanish Mediterranean coast was investigated. Potential relationships between MP ingestion and physiological and reproductive parameters in this species were also investigated. Fish stomachs were collected during routine monitoring programs for chemical contamination in 2013 (fixed in 10% *formalin* followed by storage in 95% *alcohol) and 2014* (frozen at -20° C). Making use of alkaline digestion methodology (KOH 1M, 21 days, ambient temperature) and microscope-based counting (stereo microscope) it was found that percentage of fish with MPs in its stomach was 24%, with a predominance of fibers (66%) and soft spheres (33%), representing between 1 and 8% of the total stomach content weight. We found no relationship between plastic abundance in the stomachs and gonadosomatic index and condition factor of the fish (p> 0.05). Our preliminary results generally agree with several previous investigations on plastic content in fish stomach. The identity of the removed particles and fibers await further confirmation using Fourier transform infrared (FTIR) spectrometry. These are the first observations on ingested plastic in a benthic fish species from the Western Mediterranean Sea, contributing to the knowledge about the magnitude of this environmental problem. **Acknowledgement:** This work has been supported by IMPACTA project and by the CleanSea project, part of the European Union Seventh Framework Programme (FP7/2007-2013), under grant agreement n° 308370.

MO074
An Optimised Extraction Method of Fluoranthene from Microplastics using Accelerated Solvent Extraction
J. Kandziora, TU Darmstadt; T. Schiedek, Applied Geosciences; K. Sakaguchi-Soeder, TU Darmstadt / Material Flow Management and Resource Economy
Microplastics (MPs) are a group of anthropogenic contaminants with a high persistence in the natural environment. MPs that became brittle or fragmented may release plastic additives like plasticizers, which are known to have toxic effects on the biosphere. In addition, hydrophobic toxic pollutants like polychlorinated biphenyl (PCBs) or polycyclic aromatic hydrocarbons (PAHs) in the aquatic environment may be accumulated on the surface of MPs. In order to determine the ecotoxicological impact of MPs, it is necessary to understand the nature and extent of the chemicals that travel a long distance with MPs in the environment. However, currently no harmonized analytical methods are available to extract MPs from the environmental matrix as well as to extract pollutants from the MPs. Here, we propose a reliable method to determine the mass of contaminants adsorbed onto MP using an accelerated solvent extractor (ASE). First, a series of batch experiments were carried out in the laboratory to charge fluoranthene, a 4-ring PAH, onto plastic pellets (ID < 5 mm) made of three different polymers: polyethylene (PE), polystyrene (PS) and polypropylene (PP). Then, fluoranthene adsorbed on the pellets was extracted using an ASE ® 300 (Dionex, Idstein) under a fixed pressure of 100 bar. The ASE extraction was carried out either in one or two cycles (approx. 5 minutes per cycle) at 50, 70 and 100°C depending on the physicochemical persistence of the pellets. Methanol and isopropanol were tested as solvents in this study. The ASE conditions were optimized for the extraction of fluoranthene on the surface of PE-, PS- and PP-pellets to yield a high recovery rate. First results showed that the best ASE extraction conditions for PE were at 100° C for 5 minutes in two static cycles using isopropanol, leading to an extraction efficiency of approx. 70 -80%. The similar extraction efficiency was determined for PS at 70°C, which is the maximum possible temperature for the pellets, for 5 minutes in two static cycles using isopropanol. The highest recovery rate of 110 -115% was obtained for PP under the ASE condition at 100°C in 1 static cycle using isopropanol.

MO075
Alternative pathways of microplastic exposure - microplastics and associated POPs on zebrafish gills (Danio rerio) and zebrafish eggs
A. Batel, COS University of Heidelberg / Aquatic Ecology and Toxicology; F. Borchert, H. Reinwald, COS University of Heidelberg; T. Braunbeck, University of Heidelberg / Centre for Organismal Studies
We here present an alternative pathway for the transfer of microplastics and associated pollutants by exposing zebrafish (*Danio rerio*) gills and eggs to very small microplastic particles (1-20 μm) loaded with the polycyclic aromatic hydrocarbon (PAH) benzo[a]pyrene (BaP). So far, microplastics and the transfer of associated pollutants has mainly been studied by the ingestion of microplastic particles into various organisms. Potential effects of microplastics *via* adherence to and accumulation on gills has only been studied in bivalves and crustaceans, however without analyzing the transfer of adsorbed substances. Likewise, effects by microplastics, as well as potential accumulation and transfer of pollutants to fish eggs has been neglected. Adult zebrafish were exposed to 1-5 and 10-20 μm

microparticles loaded with BaP for 6 and 24 h and analyzed for effects by both virgin and BaP-loaded microparticles on gills in the ethoxyresorufin-*O*-deethylase assay (EROD) on gills and visual fluorescence tracking of BaP. Similarly, zebrafish eggs were incubated for 96 hpf with virgin and BaP-loaded microparticles and analyzed *via* the fish embryo toxicity test (OECD 236), visual fluorescence tracking of BaP after 48, 72 and 96 hpf and the *in vivo* EROD assay after 96 hpf. Results show that microparticles mostly adhere to the mucus of fish gills and are thus subsequently washed out during exposure times. Nevertheless, there was a trend to EROD induction in gills of fish groups exposed to BaP-loaded microparticles. The fluorescence analyses located BaP on gill arches rather than on filaments, if compared to positive controls. In contrast to fish gills, microparticles readily accumulated on the chorion of fish embryos. Fish embryos showed sublethal effects following exposure to BaP-loaded microparticles, whilst virgin microplastic particles had no effect. The present study illustrates that microplastics do not only cause effects by intestinal ingestion, but also by adherence to surface structures such as gills and the egg shell. This represents an alternative exposure route to food-borne consumption of microplastics and associated pollutants.

MO076

Adsorption of four endocrine disrupting compounds on polyethylene microplastics

q. Chen; D. Yin, Tongji University / College of Environmental Science and Engineering; S. Yang, Tongji University / School of Ocean and Earth Science; S. Schiwy, Institute of Environmental Research-RWTH Aachen / Department of Ecosystem Analysis ESA; T. Seiler, RWTH Aachen University / Ecosystem Analysis; H. Hollert, RWTH Aachen University / Department of Ecosystem Analysis

Scientific studies have shown that plastics greatly contribute to the littering of the environment. Micro-sized plastics, termed as microplastics (MPPs, bisphenol A, estradiol, dienestrol, hexestrol) on polyethylene MPPs (40~48 µm) was investigated. Solution parameter effects of pH and natural organic matter (NOM) were also considered. Our results demonstrate that the adsorption isotherms of all the pollutants to MPPs complied well with the langmuir model. Q_e values decreased with pH increase (5~10), mainly due to the different speciation of compounds under different pH values. It is noteworthy that an overall trend of higher Q_e values increased with NOM increase, probably due to covalent effects.This result also implies that the presence of NOM may increase the contaminants' burden on MPPs, and subsequently increase MPPs' carrier potential for contaminants to aquatic organisms and lead to greater risks to the ecological system.

MO077

Microplastics effects and bioavailability of co-contaminants in the blue mussel Mytilus edulis

A. Catarino, Heriot-Watt University / School of Life Sciences; J. Measures, Heriot Watt University; T. Henry, Heriot-Watt University / School of Life Sciences

Microplastics (5 mm–1 µm) are the most numerous pieces of plastics reported in marine environments and concerns exist regarding their potential to affect organisms. Potential negative effects of microplastics (MPs) include disruption of gut physiology after ingestion, release of substances (co-contaminants) sorbed to MPs into organisms, and occlusion of tissue surfaces by accumulation of MPs. Mussels are particularly at risk as they filter large volumes of water and have potential to accumulate MPs on gills and/or within the gut lumen.

Co-contaminants, such as polycyclic aromatic hydrocarbons (PAHs) and metals, can sorb to MPs and desorption after MP ingestion is of toxicological concern. The objective of this study was to assess the bioavailability of associated co-contaminants to MPs in mussels, as well as to study MPs physical effects. *Mytilus edulis* mussels (one per beaker) were exposed for 24h to polyvinyl chloride (PVC) pristine particles (125-250 µm diameter), at 10 different concentrations (0-1 g/L). Co-contaminants, cadmium (Cd^{2+}) and the PAHs anthracene and pyrene, were allowed to be sorbed to MPs (>24h) prior to exposure to mussels. A dose-response according to concentration of co-contaminant while in aqueous phase was also established for mussels. Gene expression was assessed in gills and digestive gland using pi-Glutathione S-transferase (*pi-GST*) as a biomarker of PAHs bioavailability and Metallothionein-20 (*MT-20*) for Cd^{2+}. Gene expression was measured using quantitative reverse transcription PCR (RT-qPCR) after RNA extraction from gills and digestive gland. Samples of the same tissues were also placed in Davidson's fixative, sectioned and analysed to assess lesions and inflammatory responses. Preliminary results indicate that Cd^{2+} sorbed to PVC particles induced *MT-20* expression in the digestive gland of *M. edulis*: up to 5 fold change compared to control, a value within a similar range in mussels exposed to Cd^{2+} in aqueous phase (3.26 fold change in *MT-20* expression). The expression of *MT-20* increased linearly with increased particle concentration in the digestive gland, as for mussels exposed to Cd^{2+} in aqueous phase, but not in gills. Males that spawned during the experimental procedure did not exhibit *MT-20* expression in digestive gland tissues. We anticipate that our results, together with ongoing data analysis, will contribute to a better understanding of the fate and effects of MPs and their co-contaminants in the marine environment.

MO078

Microplastic may increase uptake and bioaccumulation of organic pollutants in aquatic crustaceans

C.K. Frydkjær, N. Iversen, Aalborg University / Department of Chemistry and Bioscience; P. Roslev, Aalborg University / Biology and Environmental Science

Microplastic is causing an increasing environmental problem in aquatic environments where it has been shown to enter into the food chain. Maybe even more important, microplastic may act as a contaminant trap and carrier of organic pollutants that could enhance bioaccumulation of these compounds in aquatic food chains. The uptake of microplastic in *Moina salina* was investigated using different concentrations and size fractions of microplastic particles. The amount of plastic taken up by the animals was determined by microscopy and the sublethal effects of microplastic on *Moina salina* were determined using video tracking and enzymatic assays. *Moina saliina* ingested microplastic particles at various rates in these experiments. Microplastic particles similar to the ones used for the feeding experiments were allowed to adsorb 14C-phenantrene, before these were fed to *Moina salina*. The radioactivity of the animals and of the microplastic particles was measured by liquid scintillation counting. The data obtained from these experiments were used to determine to which extent microplastic might act as a carrier of organic pollutants in aquatic environments.

MO079

Microplastics: Investigation of different effects on sorption behaviour of organic pollutants in freshwater systems

S. Huppertsberg, Hochschule Fresenius, University of Applied Sciences; S. Klein, Department of Chemistry and Biology; T.P. Knepper, Hochschule Fresenius, University of Applied Sciences

Nowadays synthetic polymers are an essential part of everyday life and an introduction of synthetic materials in the environment cannot be completely avoided. One part of this discharge are microplastic (MP) particles with diameters ≤5 mm. Due to a slow degradation, MP, as well as macroscopic plastic, has a high impact on ecosystems. Freshwater systems are a revealing field of research, as these systems play an important transport route of MP in sediments and oceans world-wide. Many aspects of the influence of MP on the environment are still under investigation and thus their effects on ecosystems are yet not fully understood. One aspect of this research is the determination of sorption properties of MP, which are based on different polymer materials such as polyethylene (PE), polypropylene (PP), polystyrene (PS), polyvinylchloride (PVC) and polyethylene terephthalate (PET). Environmental organic pollutants such as pesticides or pharmaceuticals can act as sorbate and accumulate onto MP due to hydrophobic interactions. Thus, MP may provide a transportation route for organic pollutants in aquatic systems or the food chain. Sorption processes for various organic pollutants are still under research and seem to be dependent on various parameters such as polymer material, age of the particles, biofilm formation and further environmental parameters. The aim of this study was to evaluate different synthetic polymers regarding their potential to act as sorbent for organic pollutants. Therefore, synthetic polymers were investigated in synthetic fresh water that was spiked with different micropollutants. The utilized polymer materials were polybutadiene, PS and PVC, which were each spiked with pesticides such as e.g. difenacoum and bromadiolon. The MP samples were extracted with hexane or dissolved in tetrahydrofuran and underwent purification via gel permeation chromatography and/or solid phase extraction before the content of organic pollutant was determined via GC-MS or LC-MS/MS. All polymers showed pesticide sorption and sorption isotherms were calculated for the different polymer/pesticide combinations applying *Henry, Freundlich* and *Langmuir* models. As the sorption isotherms were determined for an ideal system (synthetic polymers, synthetic fresh water), the importance and influence of further parameters have to be determined, such as the formation of biofilms and "old" MP samples.

MO080

Ingestion of environmental microplastics causes biomarker responses and behavioral changes in three-spined stickleback

G. Asmonaite, University of Gothenburg / Department of Biological and Environmental Sciences; J. Sturve, Department of Biological and Environmental Sciences; G. Limonta, B.C. Almroth, University of Gothenburg / Department of Biological and Environmental Sciences

Microplastics (MPs) raise great environmental concerns due to the wide distribution in aquatic environment and dreadful capacity to absorb and concentrate environmental contaminants. As potential threats of MPs are greatly unknown, interdisciplinary research is being accelerated towards increasing understanding of biological fate of MPs in organisms, their toxicity and inherent ecological consequences. An experimental study was conducted to study vector effects of MPs following environmentally relevant exposure scenarios. Unplasticized polyvinyl chloride (uPVC) microscopic pellets were used as model particles, which were exposed for 30 days to the effluent of sewage treatment plant and the outflow from industrial harbor in Göteborg city, Sweden. Consequently, marine adult three-spine stickleback *Gasterosteus aculeatus* were feed diets containing exposed particles. Fish were fed with experimental diets for

24 days and then potential chemical uptake and toxicity was assessed using gene and biochemical biomarkers. Additionally, behavior of exposed fish was investigated with open-field and aggression tests. Results revealed that environmental MPs can cause changes in mRNA expression levels of several genes in liver, for example, expression of metallothionein (MT) a known biomarker for metal toxicity and vittelogenin (VTG) an established biomarker for estrogenic exposure. Some changes in behavior were also observed. Further investigations are conducted to fully assess the dietary toxicity of MPs and to elucidate the composition of environmental pollutants adsorbed to MPs.

MO081

PET microplastics have no long-term effects on the freshwater amphipod Gammarus pulex

A. Weber, C. Scherer, Goethe University Frankfurt am Main / Aquatic Ecotoxicology; N. Brennholt, Federal Institute of Hydrology / Biochemistry and Ecotoxicology; G. Reifferscheid, Federal Institute of Hydrology / Department Biochemistry and Ecotoxicology; M. Wagner, Goethe University Frankfurt / Aquatic Ecotoxicology

Microplastics (MP) are abundant in most of the global marine and freshwater ecosystems and can interfere with its biota. Potential adverse effects have already been studied *in situ* as well as in laboratory studies for several marine species while effects on freshwater organisms remain so far largely unstudied. The present study provides first results on the short-term uptake and the long-term effects of PET MP on the freshwater amphipod *Gammarus pulex*. As part of an uptake study (24 hours) as well as an effect study (48 days) juvenile (6-8 mm) and adult (12-17 mm) individuals were exposed to fluorescent PET MP with a size range of 10-150 μm. Both studies covered MP concentrations from 0.4-4,000 particles per ml. The rate of MP uptake throughout 24 hours was determined by enzymatically lysing the exposed individuals and analyzing the ingested particles with a fluorescent microscope. Feeding activity, energy reserves (glycogen, lipids, proteins), moult periods and mortality were investigated in the 48-days chronic toxicity study. The results of the short-term uptake study indicate that MP ingestion by *G. pulex* is not size-selective and increases with the particle concentration. Comparing the absolute and relative uptake of adults and juveniles at same particle exposure concentrations, juveniles ingested more particles than adult individuals. In the chronic toxicity study no significant changes in feeding activity, energy reserves, moult period duration and mortality were observed in any of the treatment groups. In conclusion, this study demonstrates that a common freshwater amphipod readily ingests MP. However, the uptake does not result in adverse effects on behavioral, physiological and developmental parameters. The absence of long-term effects might be the result of the main feeding strategy of amphipods. *G. pulex* shredders detritus and plant materials and is adapted to a frequent uptake and egestion of non-digestible particles. Future studies will provide insight on whether MP adversely affect freshwater species with other feeding strategies (e.g. filter feeders).

MO082

Uptake and toxicity of methylmethacrylate-based nanoplastic particles in aquatic organisms

A. Booth, B. Hansen, M. Frenzel, SINTEF Materials and Chemistry / Environmental Technology; H. Johnsen, SINTEF Materials and Chemistry / Biotechnology and Nanomedicine; D. Altin, BioTrix

The uptake and toxicity of two poly(methylmethacrylate)-based plastic nanoparticles (PNPs) with different surface chemistries (medium and hydrophobic) was assessed using aquatic organisms selected for their relevance based on the environmental behaviour of the PNPs. Pure poly(methylmethacrylate) (medium; PMMA PNPs) and poly(methylmethacrylate-*co*-stearylmethacrylate) copolymer (hydrophobic; PMMA-PSMA PNPs) of 86-125 nm were synthesised using a mini emulsion polymerisation method. Fluorescent analogues of each PNP (FPNPs) were also synthesised using monomer 7-[4-(trifluoromethyl)coumarin]acrylamide and studied. *Daphnia magna*, *Corophium volutator* and *Vibrio fischeri* were employed in a series of standard acute ecotoxicity tests, being exposed to the PNPs at three different environmentally realistic concentrations (0.01, 0.1, and 1.0 mg L^{-1}) and a high concentration 500-1000 mg L^{-1}. In addition, sublethal effects of PNPs in *C. volutator* were determined using a sediment reburial test whilst the uptake and depuration of FPNPs was studied in *D. magna*. The PNPs and FPNPs did not exhibit any observable toxicity at concentrations up to 500-1000 mg L^{-1} in any of the tests except for PMMA-PSMA PNPs and FPNPs following 48 h exposure to *D. magna* (EC50 values of 879 and 887 mg L^{-1}, respectively). No significant differences were observed between labelled and non-labelled PNPs, indicating the suitability of using fluorescent labelling for tracing of the NPs. Significant uptake and rapid excretion of the FPNPs was observed in *D. magna*.

MO083

Effects of microplastic presence on PBDE bioaccumulation and mortality of the freshwater invertebrates Chironomus sancticaroli and Lymnaea stagnalis

A.A. Horton, Centre for Ecology and Hydrology; A. Palacio, UFPR; E. Lahive, Centre for Ecology and Hydrology; M.d. Pereira, Centre for Ecology and Hydrology / Lancaster; R.G. Disner, M.M. Cestari, M.A. Navarro-Silva, UFPR; D. Spurgeon, Centre for Ecology & Hydrology

Studies have shown that microplastic particles in the environment can associate with persistent organic pollutants (POPs) due to the hydrophobic nature of plastics and organic chemicals. This is likely the case wherever microplastics are present, given that microplastics in the environment will rarely exist in the absence of other environmental pollutants. If ingested, the gut environment of an organism may favour desorption of these adsorbed chemicals due to gut condition including pH and ionic strength and the presence of surfactants. Therefore ingestion of microplastic particles has implications for uptake and bioaccumulation of these chemicals. PBDEs (polybrominated diphenyl ethers) are widely used as flame-retardants in products such as textiles and soft furnishings, with the potential to leach into the environment, so are one of the likely POPs to find associated with microplastics. We conducted bioassays using freshwater midge larvae *Chironomus sancticaroli* and the pond snail *Lymnaea stagnalis* to observe the effects of microplastic particles (nylon < 50 μm) and PBDEs both independently and in combination, including mortality, effects on the gut microbiome, stress gene expression and PDBE bioaccumulation. Microplastic particles were mixed with quartz sand sediment at 1% concentration (13g total substrate per replicate). A PBDE mix (containing BDE-47, 99, 100, 153 and PBB-153) was added to the sediment-microplastic mix in glass vessels at six environmentally relevant concentrations (94, 188, 375, 750, 1500, 3000 ng g^{-1}). Artificial freshwater was added to each vessel once the solvent had evaporated. Given that POPs will preferentially bind to plastics over sediment, it was assumed that all PBDEs would adsorb to the nylon particles rather than the sediment or the glass vessel. Exposures ran for 96 hours during which there was no mortality effect on either species. Following the exposures RNA, microbiome DNA and tissue chemical analyses were carried out. A parallel study showed ingestion of microplastics by chironomids over a 48 hour period, with microplastics still present in the gut following a 48 hour depuration period, demonstrating that microplastics are ingested and retained. Similar observations have been made on microplastics within a pond snail gut. The results of this study will help develop our understanding of the interactions between microplastics, organic chemicals and organisms in the environment and the implications for the food chain.

MO084

Influence of microplastics on the short-term toxicity of mercury to juveniles of the sea bass (Dicentrarchus labrax)

L.G. Barboza, L.R. Vieira, ICBAS & CIIMAR, University of Porto / Department of Populations Study Lab of Ecotoxicology; L. Guilhermino, ICBAS & CIIMAR, University of Porto / Dept Populations Study Lab of Ecotoxicology

The pollution of the marine environment by microplastics is global paradigm. More knowledge on the toxic effects of microplastics alone and in mixture with other common global pollutants such as mercury are need to support environmental risk assessment of these chemicals. The objective of the present study was to investigate the influence of the presence of microplastics in the water on the short-term toxicity of mercury to juveniles of the European seabass (*Dicentrarchus labrax L.*) After acclimatization in laboratory conditions, groups of juveniles were exposed to mercury and microplastics (polyethylene microspheres 1-5 μm), alone and in mixture for 96h under controled conditions of temperature and photoperiod. Control was filtered sea water; two concentrations of mercury and two concentrations of microplastics were tested in a full factorial experimental design. Effect criteria were swimming performance and sub-individual biomarkers indicative of neurotoxicity, alterations in biotransformation, energy production, and anti-oxidant defences, and lipid peroxidation damage. For several parameters, including the swimming velocity, significant differences among treatments were found, with fish exposed to mercury alone and in the presence of microplastics showing a reduction of the predatory performance ($p < 0.05$), and impairment of several important physiological functions ($p < 0.05$). Moreover, for some of the parameters, interactions between microplastics and mercury were found. These findings highlight the need of more research on the interactions between microplastics and other common contaminants on marine organisms.

MO085

Effects of microplastics on benthic macroinvertebrates in freshwater ecosystems

L. Stuurman, P. Redondo Hasselerharm, E. Peeters, Wageningen University / Aquatic Ecology and Water Quality Management; E. Besseling, A. Koelmans, Wageningen University / Aquatic Ecology and Water Quality Management Group

Recently, the presence of microplastics (MPs) in the freshwater environment has been reported and little is known about the effects these MPs can have on freshwater organisms. It is expected that sediment-dwelling species are especially susceptible to the presence of MPs in freshwater ecosystems, as sediments could act as a sink for MPs. Previous studies done on the marine environment already showed that MPs can have an effect on benthic species, such as the reduction of fitness in the lugworm *Arenicola marina* (L.). Therefore, the aim of this study is to investigate the effects of MPs on species which are suitable for representing the freshwater benthic community. For this purpose, single-species toxicity tests were performed, where species were exposed for 28 days to 8 different concentrations of polystyrene (PS) beads with a size range of ~40-90µm. The concentrations tested in this study ranged from 0.1% to 20% (in order of percent dry weight), including the highest concentration of MPs found in the freshwater environment, which is ~1%. The dose-response relationships were calculated for each species using growth/weight as a sub-lethal endpoint and survival as a lethal endpoint. This data will be used to elaborate a Species Sensitivity Distribution (SSD), showing the differences in susceptibility for MPs between species. The SSD can also be used in the future to determine the maximum allowable concentration of MPs in the freshwater environment.

MO086
Decreased feeding or food assimilation is a likely physiological mechanism of microplastic effects in the filter-feeding crustacean Daphnia magna
L.N. Trac, Danish Technical University; F. Khan, Roskilde University / ENSPAC; K. Syberg, Roskilde University / Department of Environmental Social and Spatial Change; A. Gergs, gaiac - Research Institute for Ecosystem Analysis and Assessment / Department of Environmental Social and Spatial Change; A. Palmqvist, Roskilde University / Department of Environmental Social and Spatial Change
Marine and freshwater contamination with microplastic (MP) has received increasing focus during recent years. For example ingestion of MP by various filter-feeding organisms including the freshwater cladoceran *Daphnia magna* has been documented. However, we still have limited knowledge of MP effects in freshwater environments. In theory MPs may affect exposed organisms by four different mechanisms: 1) ingestion of MPs decrease food intake by interfering with feeding or filling up the gut, 2) MPs may in other ways interfere mechanically with the physiology of the organisms, 3) toxic additives (e.g., plasticizers) may leach from ingested particles, 4) environmental chemicals may adhere to particles leading to changed (i.e., increased or decreased) uptake of the chemical in question. The purpose of the present study was to test the hypothesis that MPs interfere with feeding or food assimilation leading to effects at the organism level and eventually to potential population-level effects. Two experiments were carried out according to a slightly modified *D. magna* reproduction test (OECD 211). Experiment 1 tested potential effects of particle size (1-10 and 10-106 μm), using 0.96 g/cc polyethylene (PE) beads. Experiment 2 tested effects of particle density using PE beads in the same size range (10-90 μm) but with different densities (ca. 1.00 and 1.10 g/cc). In both experiments survival, growth and reproduction was measured during a 21 days study. The study was a proof-of-principle study using particle concentrations (i.e., 1000 and 10,000 particles/ml) above likely realistic environmental concentrations. There were no significant effects of MP exposure on *D. magna* survival regardless of particle size or density. Growth (after day 15) and reproductive output were decreased significantly by the MP particles with the highest density, but not by any of the other particle types. The fit of a dynamic energy budget model indicated that the observed effect was caused by either a reduction in feeding or food assimilation or by increased maintenance cost. The study shows that impacts of plastics depend crucially (though not surprisingly) on plastic properties such as density, and that certain properties (e.g., size) are unimportant if particles end up in a different environmental compartment than the organism. The next step should be to test other combinations of particle size, density and potentially shape at environmentally realistic particle concentrations.

MO087
Microplastics in rivers: Focus on short-term temporal and spatial variabilities
R. Dris, ParisEst University; j. gasperi, LEESU / LEESU laboratoire eaux environnement et systèmes urbains; B. Bounoua, ParisEst University / LEESU laboratoire eaux environnement et systèmes urbains; V. Rocher, SIAAP; B. Tassin, Leesu - Enpc / LEESU laboratoire eaux environnement et systèmes urbains
Microplastics in freshwater is an increasing issue. These plastics defined as a particle with a size smaller than 5 mm have been widely reported in marine environments. This study aims at investigating the homogenity of microplastic distribution in rivers and also to evaluate the short tem and spatial varaibility of microplastics in rivers. The Marne river was considered. The samplings were performed with a plankton net (mesh size 80 μm). Two separate campaigns were carried out in order to assess the short-term variability of the microplastic concentrations. Six samples were collected per campaign. On the first campaign, each sampling was performed during 1 minute while it was performed during 3 minutes on the second campaign. For the variability through the cross section, triplicates in five different points were sampled. The sampling duration was 3 minutes. Three points of sampling were on the surface with one in the right bank, one in the left bank and one in the center. The two remaining points were in the center with respectively 1 and 2 meters of depth. The depth of the water at the moment of the sampling was 2.6 m. During short-term temporal variability tests, concentrations ranged between 38.2 and 101.6 particles/m^3 in the first campaign with a coefficient of variation around 45% and between 18.7 and 38.6 particles/m^3 during the second with a coefficient of variation of 26%. The water flow was also different. In fact, the second campaign was carried out after a month of particularly dry weather leading to a very low water flow. Microplastic concentrations seem to be more variable in high water flow conditions. A lateral variability (n=9) of 53% is found. The higher concentrations observed near the banks might be related to the effect of the intense fluvial traffic in the Parisian agglomeration. In fact, it can expected that a barge passing generates waves that drive microplastics and floating debris towards the banks. Considering all samples collected in the middle of the river, a coefficient of variation of 21% (n=9) is found which shows that the vertical variability is more than two times lower than the lateral variability. This result is not surprising knowing that in river conditions, a constant water mixing is induced by the currents and reduces the chances of stratification. Moreover, the passing of the barges can easily contribute to this mixing.

MO088
Microscopical investigations of polystyrene microparticles colonization by Vibrio crassostreae
V. Foulon, LEMAR - UMR 6539; F. Le Roux, UPMC-CNRS UMR 8227; P. Soudant, I. Paul-Pont, LEMAR UMR 6539 CNRS/UBO/IRD/Ifremer; A. Huvet, Ifremer, LEMAR UMR 6539 CNRS/UBO/IRD/Ifremer; C. Lambert, LEMAR UMR 6539 CNRS/UBO/IRD/Ifremer
Microplastics represent a widespread contamination in the global environment, particularly documented for the oceans. Recent studies of microorganisms' diversity associated with microplastics show a large presence of bacteria of the genus *Vibrio*. Particularly, some species pathogenic for marine organisms were identified associated to microplastics collected at sea. These discoveries raise questions about the potential role of microplastics as a vector for pathogenic organisms in the marine environment. A protocol to study the colonization of polystyrene (PS) in controlled conditions was designed, with the aim to understand factors modulating the adhesion on these microparticles. The pathogenic bacteria *Vibrio crassostreae* J2-9 was used in this study owing to its pathogenicity for oysters *Crassostrea gigas*, and constitutive mutants expressing GFP (Green Fluorescent Protein) were constructed to follow the colonization using fluorescent microscopy. Colonization processes and dynamics were investigated *via* confocal fluorescent microscopy and scanning electron microscopy for different types of polystyrene microparticles (smooth, irregular, fluorescent and non-fluorescent) over 24h to 96h. Incubations were performed in different media to assess the influence of some abiotic (presence of nutrients) and biotic (presence of multi-species microorganisms associated with natural seawater) parameters. The results of this study highlight complex processes of colonization/decolonization: for all particles types the percentage of colonised particles was higher in a Zobell culture media rich in nutrients as compared with filtered synthetic seawater. Roughness of the particles led to a better colonization than what was observed for smooth PS microbeads. In natural seawater, presence of natural agregates formed by debris and microorganisms around the particles led to a strong and long lasting colonization, suggesting that *V. crassostreae* could play a role as a second colonizer in the marine environment. The knowledge developed during this study opens the way for further studies addressing this topical issue. **Key words**: microplastics, polystyrene, *Vibrio,* colonization

MO089
The effects of microplastic on fresh water Hydra attenuata morphology & feeding
F. Murphy, Uninversity of the West of Scotland / Institute of Enviromental Biomedical Health Research; L. Prades, University of the West of Scotland / Institute of Enviromental Biomedical Health Research; C. Ewins, B. Quinn, University of the West of Scotland / Institute of Biomedical and Environmental Health Research
Microplastic refers to small pieces of plastic Hydra attenuata. Microplastics (polyethylene) used were sourced by vacuum filtering a face wash product containing microbeads. *Hydra* were then exposed to different concentrations of these microplastics (Control, 0.01, 0.02, 0.04, 0.08 g/ml) and morphology was recorded at 24, 48, 96 hrs and 1 week. Feeding tests were also carried out using the same concentrations as the exposure by recording the amount of *Artemia* ingested over a period 120 min. *Hydra* were found to be able to ingest the microplastics (22 - 444 μm) and feeding was affected by the presence of microplastics even at the lowest concentration used (0.01 g/ml). After 60 min of exposure the *Hydra* ingested a lower amount of *Artemia* at all concentrations of microplastic compared to the control. This became particularly evident at the 90 and 120 min mark. Exposure to the microplastics did cause changes to the morphology of the *Hydra*, however these changes were non-lethal. The preliminary results of this study show that *Hydra attenuata* are capable of ingesting microplastics. The presence of microplastics disrupted the feeding behaviour of the *Hydra* thus negatively impacting its ability to feed. Continued research in this area will provide valuable insight in determining the potential impact microplastic can have on the health of freshwater biota.

MO090
Quantification of microplastics emissions from cosmetic products to freshwater ecosystems
G. Kalcikova, A. Žgajnar Gotvajn, University of Ljubljana / Faculty of Chemistry and Chemical Technology
Recently, a lot of attention has been put on small pieces of plastic materials

commonly called “microplastics”. There are two sources of microplastics; microplastics generated through fragmentation of larger plastic material called secondary microplastics and primary microplastics – particles manufactured at a specific size range usually used as abrazives (microbeads) in cosmetic products. After usage of these products, microbeads are released into sewage and travel across wastewater treatment plant and are finally discharged into surface waters. However, the amount of microbeads released into the environment has not been yet assessed. Hence, the aim of our study was to estimate amount of microbeads that can daily be released from cosmetic products to surface waters. The study initially characterized the microbeads from cosmetic products with an emphasis on physical properties and particle size distribution and consequently quantified the daily emission of microbeads from consumers by a questionnaire survey. Amount of microbeads in five selected scrubs varied across products, but the highest amount of microbeads was 11% of the cosmetic product. All microbeads were made of polyethylene with the major particle size up to 100 μm. Survey participants (n =178) were estimated to release 15 mg of microbeads per person per day. If wastewater treatment plant efficiency (~ 70% microbeads removal) is taken into account the daily emission of microbeads into surface waters is 4.5 mg of microbeads per person being potentially more than 2 tons of microbeads per day released in the European Union. Results of our study showed, that microbeads from cosmetic products can represent a potential threat for freshwater ecosystems, because they are continuously introduced into surface waters and due to their small size (up to 100 μm), they can be easily ingested by a range of aquatic organisms.

Behavior Revised: Examining Behavioral Effects of Contaminants and Other Stressors in Aquatic Animals (P)

MO091

Impact of the antidiabetic drug metformin on brown trout

S. Jacob, Universität Tübingen / Animal Physiological Ecology; R. Triebskorn, University of Tuebingen / Animal Physiological Ecology

With a focus on two groups of emerging micropollutants in aquatic environments, food additives and pharmaceuticals, the project Eff-Net crosses the borders between (natural and socio-political) science and public interest by providing an analytical network, which gives insight into the cross-linking of consumer behaviour and ecological impact. In a multi-disciplinary approach, antidiabetics (e.g. metformin), artificial sweeteners (e.g. sucralose) and antidepressants (e.g. fluoxetine) as well as their metabolites and transformation products are studied from the mode of action at the molecular level up to the effects at the community level. In the present study, we investigate possible effects of metformin, an antidiabetic drug, in brown trout (*Salmo trutta* f. *fario*). The influence of different temperatures is also addressed. Starting with the exposure of fertilized eggs, developing eggs and juvenile fish are continuously exposed to different concentrations of metformin (1x, 10x, 100x and 1000x the environmental concentration). The experiment is conducted at two different temperatures, regarding possible interactions of chemical toxicity and temperature. To show influences on embryo development, mortality, hatching success, and time of hatch are recorded. At the end of the sac-fry stage, several endpoints indicating fish health are investigated: these include the histological condition of liver, glycogen storage in this metabolic organ and alterations in the level of the stress protein Hsp70. Additionally, animal behaviour (swimming velocity and predator-prey-interaction) is investigated. The information gained from this experiment at the organismic level is used to validate results of experiments addressing effects at the molecular and community level (generated in parallel by other partners of Eff-Net) with respect to their ecological relevance.

MO092

Sublethal effects of the combined exposure to metal mixtures and predator stress on Asellus aquaticus

M. Van Ginneken, University of Antwerp, Dept. Biology / Biology SPHERE; R. Blust, L. Bervoets, University of Antwerp / Systemic Physiological and Ecotoxicological Research   Department of Biology

In aquatic ecosystems, trace metals often occur in mixtures in which they can strongly interact with each other, creating synergistic, additive or antagonistic toxic effects. Moreover, natural stressors such as temperature fluctuations or predators are present, which can increase the animals' vulnerability to these contaminants. However, classic toxicity tests are performed using single compounds without additional stressors and could thus lead to an over- or underestimation of the impact of metal exposure in the natural environment. This study investigates the effects of the combined exposure to predator stress and metal mixtures of copper, cadmium and lead on the freshwater isopod *Asellus aquaticus*. The chosen metal concentrations are equal to and tenfold of the environmental quality standards (EQS): 7 and 70 $\mu g.L^{-1}$ for Cu; 0.15 and 1.5 $\mu g.L^{-1}$ for Cd; and 7.2 and 72 $\mu g.L^{-1}$ for Pb. Animals were exposed to the different metals separately as well as to binary and tertiary mixtures. These metal treatments were combined with two predator treatments in which cues of both fish and invertebrate predators were absent or present. After ten days, various sublethal endpoints were assessed. Besides determining the metal accumulation and the growth rate of each animal, we mainly focused on behavioral endpoints such as swimming performance and feeding rate. Furthermore, the energy reserves (glycogen, protein and lipid concentrations), oxidative stress (SOD, CAT and TBARS) and respiration were measured. We hypothesized that metal accumulation, respiration and oxidative stress would be higher in the animals of the (metal) treatments with predator stress. However, we expected the animals of the treatments without predator cues to have higher feeding and growth rates, higher energy reserves and to be more active. This study will help to understand how anthropogenic and natural stressors interact and contribute to the development of ecologically relevant EQS.

MO093

Sublethal Effects of Glyphosate and Glyphosate-Copper Complexes to Daphnia magna Determined by Video Tracking and Behavior Analysis

L. Rykær Hansen, P. Roslev, Aalborg University / Biology and Environmental Science

Glyphosate (N-(phosphonomethyl)glycine) is the active ingredient in a range of popular broad-spectrum herbicide formulations. Glyphosate is a chelating agent (ligand), and can form complexes with divalent metal ions including copper (Cu). The toxicity of glyphosate to non-target organisms has been evaluated in previous studies, however, little is known about the bioavailability and ecotoxicity of glyphosate:copper complexes to non-target organisms. We have used video tracking to quantify behavioral changes in *Daphnia magna* after exposure to glyphosate and glyphosate:Cu(II) complexes. Behavioral responses were quantified for individual juvenile *D. magna* after exposure for 24 h and 48 h. Sublethal concentrations of glyphosate:Cu (II) resulted in decreases in swimming velocity, acceleration speed, and distance moved whereas the inactive time of *D. magna* increased. Active/inactive time and distance moved were the most responsive parameters to glyphosate:Cu(II) exposure. On a molar basis, glyphosate:Cu(II) complexes were more harmful to *D. magna* than glyphosate alone. The EC50-48 h for a 1:1 mixture of glyphosate and Cu(II) was 13.8 μM and 9.8 μM determined as change in active time and distance moved, respectively. In comparison, visual observation of immobility resulted in an EC50-48h of 25.5 μM. The video tracking results indicated that exposure of *D. magna* to binary mixtures of glyphosate and Cu(II) attenuated acute metal toxicity but increased apparent glyphosate toxicity due to complexation. The results suggest that glyphosate is a likely mediator of environmental metal toxicity, and that video tracking provides an opportunity for quantitative studies of sublethal pesticide effects to non-target organisms.

MO094

Are we mainly looking at the bright side of life? The role of food as an exposure pathway

M. Bundschuh, Department of Aquatic Sciences and Assessment Swedish University of Agricultural Sciences / Department of Aquatic Sciences and Assessment; J. Zubrod, R. Bundschuh, Institute for Environmental Sciences University of Koblenz-Landau / Institute for Environmental Sciences; D. Englert, Institute for Environmental Sciences / Institute for Environmental Sciences; A. Feckler, Swedish University of Agricultural Sciences (SLU) / Department of Aquatic Sciences and Assessment; R.B. Schaefer, R. Schulz, University of Koblenz-Landau / Institute for Environmental Sciences

The ecotoxicological testing of chemicals is mainly focusing on waterborne exposure pathways. Considering the physicochemical properties but also the mode of action of some chemicals, however, their impact via the ingestion of contaminated food or their implications for the nutritious quality of food may have serious influences on the behavior and physiology of aquatic organisms. We will demonstrate that chemicals with a high affinity towards organic carbon (i.e., lambda-cyhalothrin) adsorb to food, which ultimately potentiates the effects caused by the waterborne effect pathway. Moreover, systemic pesticides such as neonicotinoids but also insecticidal proteins, produced by genetically modified plants, showed a higher toxic effect when organisms fed on related plant material compared to the water-borne toxicity of leached chemicals. This suggests that the compounds are bioavailable to the test species during gut passage, a process not reflected in standard toxicity tests. Moreover, substances targeting autotrophic (e.g., herbicides) or heterotrophic microorganisms (e.g., antibiotics and (in)organic fungicides) can affect the quality of the food for the next trophic level, namely grazing and leaf shredding invertebrates. Experimental efforts have largely focused on heterotrophic microorganisms and shredders. These data suggest on the one hand that shredders can sense toxic effects on heterotrophic biofilms associated with organic matter because they showed preferential feeding on non-contaminated food with a presumably higher nutritious quality. On the other hand, the organisms’ energy processing and physiological fitness can be substantially influenced when dependent on food with a modified heterotrophic biofilm. This may ultimately cause bottom up directed effects in heterotrophic food webs. We discuss the relevance of the food-related exposure pathway with respect to empirical evidence and the broader ecological context.

MO095

Spontaneous Locomotor Changes in Zebrafish (Danio rerio) when chronically exposed to Chemical Warfare Agents (CWAs) found in the Baltic

Sea.

M.S. Storgaard, Aarhus University, Department of Environmental Science / Department of Environmental Science; H. Sanderson, Aarhus University Department of Environmental Science / Department of Enviromental Sciences; E. Baatrup, University of Aarhus / Zoophysiology Dept

After the 2nd World War the CWAs were prohibited by law and 11,000 tonnes of toxic agents were dumped in the Bornholm Basin east of Bornholm. The dumped chemical munitions have not reached attention from politicians and scientists until recently. During earlier projects, such as MERCW (2005-2008) and CHEMSEA (2011-2014), the area has been screened for the presence of parent compounds and metabolites including the concentrations they are found in. The majority of the detected compounds has been found in the sediment and a minor part in the pore water. The (eco)toxicity of these compounds remain to be illuminated in which this study hopefully will contribute to. Especially, chronic toxicity needs to be described as this mimics a more environmentally realistic situation. One or two compounds will be accessed based upon various factors such as detection frequencies, found concentrations in both sediment and pore water, acute toxicity and physicochemical properties. Besides the mentioned evaluation factors, Sulphur mustard (Yperite) degradation products will have emphasis as the majority of the dumped CWAs is the sulphur mustard gas. The chronic toxicity will be described by spontaneous locomotor changes in Zebrafish (*Danio rerio*). The CTDB database and Zebrafish gene collection reveals that genes associated with locomotion interacts with some of the found parent and degradation compounds of CWAs; even though the locomotion is a complex out of an array of genes. This study intends to draw lines to the commercially important cod (*Gadus morrhua*). The cod migrates down to the seafloor – even crossing the oxycline - where the CWA munitions were dumped. To sum up, this study will obtain novel ecotoxicity data on recently discovered degradation products and assess the potential threat to the commercially important cod (*Gadus morrhua*). This study is a part of the NATO Science for Peace and Security (SPS) project "Towards the Monitoring of Dumped Munitions Threat" (MODUM).

MO096

Waterborne toxicity and altered food quality affect the food-processing behavior and physiology of Asellus aquaticus - implications for food webs in streams

A. Feckler, Swedish University of Agricultural Sciences (SLU) / Department of Aquatic Sciences and Assessment; W. Goedkoop, Swedish University of Agri Sciences / Department of Aquatic Sciences and Assessment; J. Zubrod, Institute for Environmental Sciences University of Koblenz-Landau / Institute for Environmental Sciences; R. Schulz, University of Koblenz-Landau / Institute for Environmental Sciences; M. Bundschuh, Department of Aquatic Sciences and Assessment Swedish University of Agricultural Sciences / Department of Aquatic Sciences and Assessment

The breakdown of terrestrially derived leaf litter is a key ecosystem process for energy provisioning in headwater streams mediated by microbial decomposers and detritivorous, leaf-shredding macroinvertebrates. Stressors like fungicides, however, can impact the functions of these decomposer-detritivore systems via indirect and direct pathways. To disentangle the relevance of each pathway, a 2x2-factorial test design was applied: leaf litter was conditioned under exposure to the model fungicide epoxiconazole (0 and 15 μg/L) and fed to the shredder *Asellus aquaticus*, kept under control conditions or exposed to the same epoxiconazole concentration over 28 days. Endpoints were chosen related to the conditioning status of leaf material as well as the food-processing and physiology of *A. aquaticus*. When fed with fungicide-affected leaf litter, *Asellus* increased consumption (5%) and depleted excretion (20%) compared to the control, indicating compensatory feeding and enhanced utilization of the ingested food. This behavior may have been triggered by a lower leaf-associated microbial biomass (fungi: 25%; bacteria: 15%) after conditioning under fungicide exposure. Reduced growth (30%) and lipid content (8%) of asselids, however, suggest these processes to be insufficient to fully compensate for the energy requirements. Hence, dietary fatty acids (FA) essential for asselids' growth might have been additionally used as an energy source, given the lower essential FA contents (10%) compared to control organisms despite a higher availability of FA on the leaf material. Waterborne exposure led to an increased assimilation of the ingested food, judged by lowered consumption (5%) and excretion (10%). Due to reduced growth (37%) and lipid content (21%), this compensational mechanism was judged insufficient, as it induced a mobilization of internal energy reserves to cope with chemical stress. For the combined (worst-case) scenario an additive action of both pathways was found: compared to the control, asselids' consumption and excretion were reduced by 17% and 15%, respectively. Similarly, depletions were found for growth (44%) and lipid content (28%). These results suggest that fungicides have the potential to affect the ecosystem functioning of decomposer-detritivore systems via several pathways. A more comprehensive understanding of each pathway's relevance seems therefore fundamental to accurately predict effects on energy provisioning in heterotrophic stream food webs.

MO097

Migratory behavior, metabolism, oxidative stress and mercury concentrations in marine and estuarine European glass eels (Anguilla anguilla)

V. Bolliet, UMR ECOBIOP INRA - Université de Pau; J. Claveau, UMR ECOBIOP; P. Gonzalez, CNRS UMR 5805; M. Baudrimont, Université Bordeaux1; M. Monperrus, Laboratoire de Chimie Analytique BioInorganique et Environnement LCABIE

This study investigate the relationships between the estuarine migratory behavior, Methylmercury (MeHg) concentrations, oxidative stress response and detoxification processes in glass eels, collected in marine and estuarine waters at the end of the fishing season (April). Glass eels migratory behavior was investigated in an experimental flume according to their response to dusk. Fish responding to the decrease in light intensity by ascending in the water column and moving with or against the flow were considered as having a high propensity to migrate (migrant). Glass eels still sheltering at the end of the 24 hrs catching period were considered as having a low propensity to migrate and were called non-migrant. Our results provide some evidences that estuarine glass eels present a higher propensity to migrate and lower indications of oxidative stress than marine glass eels. This might reflect a selection process, non migrant marine glass eels progressively settling in the estuary and/or a change in feeding behaviour. Indeed, in April, glass eels restart feeding in the estuary which might decrease the oxidative stress related to starvation, and enhanced migration. There was no difference in MeHg concentrations between migrant and non migrant glass eels. However, it is suggested that non migrant glass eels might present a higher vulnerability to stress (at least contamination and/or starvation), although the underlying mechanisms remain to be elucidated.

MO098

Behaviour as a Tool to Assess the Effects of Environmental Contaminants in Crustaceans: A Review

S.A. Kohler, University of Portsmouth / Biological Science; M.O. Parker, University of Portsmouth; G.J. Watson, University of Portsmouth / Institute of Marine Sciences; A. Ford, University of Portsmouth / Biological Sciences

Behavioural effects have been used in toxicology testing since the 1960s as they provide a link between biochemical and ecological consequences of environmental contaminants. A review was conducted, totalling over 70 papers on behavioural ecotoxicology in crustaceans to determine the main behavioural endpoints developed and any gaps in the current literature. Studies on behavioural effects are known to be fast and highly sensitive, with reported effects at concentrations up to 1000 fold lower than lethal concentrations. Despite this, standard ecotoxicology testing using acute lethality and chronic effects on growth, development, and reproduction have historically been used to define environmental quality standards. Behavioural endpoints have received far less attention largely due to a lack of the necessary tools to facilitate these studies. Recent computational advances have facilitated an increase in behavioural ecotoxicology due to a capacity to quantify a range of sensitive endpoints. This review has highlighted that most of the work in crustaceans has focused on swimming and avoidance behaviours (49% and 21% respectively). However, there are a large number of other quantifiable endpoints including reproduction, aggression, feeding, anti-predator and types of taxis. With closely related endpoints such as phototaxis and anxiety-like behaviours there is a need for clear definitions and carefully planned experiments for appropriate interpretation of effects. While there have been a wide variety of species used in these studies, endpoints were often species-specific and associated with the life history of the crustacean (e.g., mate guarding). Most studies have focused on traditional contaminants, such as heavy metals (37%), pesticides (27%) and PAH's (20%), with a recent increase in novel compounds. Behavioural assays have been used extensively in pharmacological testing. Despite being translated to environmental toxicology of fish, they are yet to be fully optimised to other taxa. With advances in the technology to facilitate behavioural studies in ecotoxicology, there is the potential for developing high-throughput techniques that measure multiple behaviours in crustaceans. However these are yet to be fully optimised and validated.

MO099

Behavioral and morphological responses of crucian carp (Carassius carassius) exposed to the antidepressant fluoxetine under predation risk

O. Berglund, J. Örjes, C. Brönmark, K. Hulthen, Lund University / Dept of Biology

Due to their potential for affecting the modulation of behavior, the effects of selective serotonin reuptake inhibitors (SSRIs) in the environment are particularly interesting with regard to interspecies interactions, and the non-consumptive effects induced by predators in prey organisms. Here, we tested the effects of the SSRI fluoxetine on fitness related behavioral and morphological traits of the crucian carp (*Carassius carassius*) in the presence or absence of a natural predator, the northern pike (*Esox lucius*). The crucian carp is known to change behavior (i.e. boldness and sociability) and morphology (body shape) in the presence of predators. Effects on crucian carp boldness, sociability, body weight and shape were recorded after short-term (two weeks) and long-term (three months) exposure to fluoxetine at 1 and 100 μg/L, and interactive effects with the added stress of predator presence were evaluated.

MO100
Sewage treatment works' effluent affects activity of Gammarus pulex (Amphipoda)
A. Love, Sparsholt College / School of Biological Sciences; A. Ford, University of Portsmouth / Biological Sciences; N. Crooks, University of Brighton / School of Pharmacy and Biomolecular Sciences
The effluent of sewage treatment works (STW) is a complex mixture of domestic and industrial compounds, including pharmaceuticals, which have the capacity to disrupt the normal functioning of aquatic organisms. For the first time, the impact of these effluents on the activity of a freshwater amphipod has been quantified. *Gammarus pulex* were exposed to the effluents of two similar STW at levels of 50%, 100% and controls for 7 days. Measurements of distance travelled (mm) and velocity (mm s^{-1}) of individual shrimp were taken with the Noldus Danio Vision Behaviour system after 0h, 2h, 24h and 7d intervals. Readings were taken every 0.016s for 4 minutes with alternating sequences of 60 seconds light:dark. There was no significant difference found between the velocity nor distance between any test groups. However, there was significant differences seen in the 'acceleration' and 'deceleration' responses of *Gammarus*: individuals exposed to both effluents moved further and faster in the first 5 seconds the lights were switched on (P< 0.01). Typically, *Gammarus* maintained in 100% effluent increased (in both velocity and distance travelled) by ~40% compared to controls after 7 days. Significant differences between treatment groups developed after 24h exposure, were more pronounced after 7 days, and the effect was greater with increasing concentrations of effluent. Similarly, the activity of effluent-exposed animals did not diminish after the lights were switched off. For example, in the first 5 seconds of darkness animals in the 100% exposure group had an average velocity of 13.2mm s^{-1} compared to 5.3 mm s^{-1} in the control group. The increase was significant in one effluent (P< 0.01) but was not seen in the other effluent. There have been other reports of pharmaceuticals at environmentally relevant concentrations affecting the activity of amphipods. This study suggests that STW effluents can have a similar impact. As a negatively phototaxic species, any influence on the response of *Gammarus* to light could have wider ecological repercussions. Ongoing studies are investigating the behavioural response to specific pharmaceuticals.

MO101
Temporal profiles of behavioral alterations in zebrafish embryos and larvae exposed to pharmaceuticals
C. Di Paolo, RWTH Aachen University / Ecosystem Analysis ESA; M. Krauss, Helmholtz centre for environmental research - UFZ / Effect Directed Analysis; M. Fenske, Fraunhofer Gesellschaft IME / Translational Medicine and Pharmacology; I. Werner, Swiss Centre for Applied Ecotoxicology / Department of Anatomy Physiology and Cell Biology; H. Hollert, RWTH Aachen University / Department of Ecosystem Analysis
The occurrence of neuroactive chemicals in aquatic environments is of growing concern due to the risks posed to humans and other animals. Aquatic organisms are particularly vulnerable due to their continuous exposure to variable mixtures of pollutants. In fact, recent studies demonstrated that environmentally relevant concentrations of neuroactive pharmaceuticals can affect population-relevant fish behavior such as aggression, feeding and reproduction. There is a need to develop and improve bioassays that can support the evaluation of neuroactive environmental contaminants on fish behavior. In this study, we investigated the temporal profiles of behavioral effects in zebrafish *Danio rerio* early life stages after static exposure to neuroactive pharmaceuticals. Zebrafish embryos and larvae up to 5 days post fertilization (dpf) were exposed to venlafaxine (serotonin norepinephrine reuptake inhibitor antidepressant), carbamazepine (voltage-gated sodium channel inhibitor and GABA receptor agonist anticonvulsant) and oxazepam (benzodiazepine derivative anxiolytic) at concentrations in the μg/L range (1 nM -10 μM). The selected compounds are relevant aquatic contaminants, and concentration ranges are representative of environmental situations. Embryos and larvae were exposed for short (during 24 h) and prolonged (starting at day 0) exposure periods, simulating acute and chronic exposure scenarios. Behavior was assessed at embryonic (2 to 3 dpf) and larval (5 dpf) stages. The following behavioral endpoints were measured: photomotor and startle responses (both embryos and larvae), and phototaxis and thigmotaxis reactions (larvae only). Exposure concentrations were measured at the beginning and at the end of exposure by LC-MS/MS. Results of this study are discussed regarding their ecotoxicological implications and environmental relevance. In addition, the methodological aspects for the application of behavioral assays in future ecotoxicological studies are considered.

MO102
EFFECTS OF NATURAL DYE ERYTHROSTOMINONE AND SYNTHETIC BASIC RED 51 ON ZEBRAFISH EMBRYOS DEVELOPMENT AND LARVAE BEHAVIOR
F.R. Abe, University of São Paulo USP / Faculdade de Ciências Farmacêuticas de Ribeirão Preto; A.R. Almeida, C. Gravato, University of Aveiro / Department of Biology and CESAM; A.M. Soares, Universidade de Aveiro / Department of Biology and CESAM; D.P. Oliveira, University of São Paulo USP / Faculdade de Ciências Farmacêuticas de Ribeirão Preto
Organic compounds present in natural sources have been used in several experimental conditions aimed to develop safe human health dyes as alternative to replace synthetic dyes, since these are precursors of mutagenic compounds. Nonetheless, in addition to a safe human health dye, an eco-friendly dye is desirable to be used by industry, once the international scientific community is concerned about environmental health protection. Thus, toxicity tests to non-target organisms have been used to evaluate adverse effects of dyes to the ecosystem. Zebrafish embryos (*Danio rerio*) are becoming an important alternative model in ecotoxicology due to its easy maintenance and breeding, likewise a well characterized early development and transparent embryos, which allow us to easily analyze survival, morphological alterations, and behavior. This study aimed to assess and compare the effects of the natural dye erythrostominone (ERY – extracted from microorganisms), its photodegraded product (DERY), and the synthetic dye Basic Red 51 (BR51 – used in cosmetic industry) on development of embryos and behavior of larvae of zebrafish. Zebrafish embryos were exposed to different concentrations of ERY, DERY and BR51. Hatching success, coagulation, edemas, malformation and mortality of embryos were recorded daily until 96 h post fertilization (hpf) in a stereomicroscope (SMZ800, Nikon) with coupled camera (Nikon LV-TV, Japan). Behavior was assessed by measuring the locomotor activity (total swimming distance, time, activity and velocity) of zebrafish larvae at 144 hpf exposure to sub-lethal concentrations of ERY, DERY and BR51, using ZebraBox and ZebraLab software (ViewPoint Life Science, Lyon, France). All tests were performed under controlled temperature (26ºC ± 1) and dark incubation in order to avoid degradation of ERY and BR51 or further degradation of DERY. Our results showed that both ERY and BR51 affected yolk sac morphology of embryos of zebrafish with LOEC of 7.5 mg/L. ERY also induced the formation of edemas on embryos of zebrafish exposed to concentrations above 7.5 mg/L. Moreover, behavior was impaired on larvae of zebrafish either exposed to ERY or BR51. Interestingly, DERY did not affected the parameters tested with embryos and larvae of zebrafish, suggesting that degradation of ERY is sufficient to prevent toxic effects induced by ERY. Thus, ERY could be potentially used as an alternative dye.

MO103
Chemosensory responses to thyroid hormone and thyroid hormone disruptors in North American bullfrog (Lithobates catesbeianus) tadpoles
J. Heerema, University of Lethbridge / Biological; C.C. Helbing, University of Victoria / Department of Biochemistry Microbiology; G.G. Pyle, University of Lethbridge / Biological Sciences
Endocrine disrupting compounds (EDCs) enter wastewater through anthropogenic sources and are not fully removed by wastewater treatment processes. As a result, EDCs are persistent in wastewater effluent at low concentrations and can still be biologically active. Consequently, EDCs are able to disrupt the endocrine system, which regulates growth and development in vertebrates. Some EDCs are thyroid active, and therefore can have agonistic or antagonistic effects on the thyroid system. The normal functioning of the thyroid hormone (TH) is important in vertebrates during early life stages for the development of many organs and tissues. The present study investigates the effects of THs and EDCs on chemosensory acuity in North American bullfrog (***Lithobates catesbeianus***) tadpoles. Amphibians are good sentinels for studying the effects of TH disruption because metamorphosis is almost entirely dependent on THs. Furthermore THs drive the development and remodelling of the entire olfactory system in tadpoles during metamorphosis. As a result, TH disruption has the potential to affect chemosensory acuity in tadpoles after exposure to EDCs. In this study premetamorphic tadpoles were exposed to environmentally relevant concentrations of thyroxine (T4), triiodothyronine (T3), and 17β-estradiol (E2) in the presence and absence of T3 and T4, as well as a cocktail of known EDCs. After exposures, behavioural experiments were used to detect changes in chemosensory acuity using I-maze behavioural arenas. A mixture of amino acids our lab has shown to elicit an avoidance response in bullfrog tadpoles was administered into the I-maze and the tadpole's response to the chemosensory cue was measured by tracking its position in the I-maze. Changes in chemosensory acuity and behavioural responses to TH disruption can serve as a strong link between TH disrupting chemicals and adverse ecological effects. In an aquatic environment chemical signals provide organisms with important information about nearby predators, mates, or food. Therefore, a change in chemosensory acuity can lead to adverse ecological effects. Studying changes in chemosensory acuity will provide a greater understanding of the ecological significance of EDCs present in wastewater and the implications their presence may have on amphibian populations in receiving waters.

MO104
Behavioral ecotoxicology modeling of freshwater clam valve rhythm in response to waterborne copper
L. Jou, National Ilan University; B. Chen, MingDao University; W. Chen, Kaohsiung Medical University / Department of Biomedical Science and Environmental Biology; C. Liao, National Taiwan University / Department of Bioenvironmental Systems Engineering
Various chemical analysis methods are labor-intensive, costly, and are not suitable

for application to the continuous and real-time *in situ* monitoring of water quality. The Asian clam, *Corbicula fluminea*, a filter-feeding bivalve living in the upper layers of sediments, is an economically important species with a wide distribution throughout the world. Because of their wide distribution, ease of collection, environmental sensitivity, and ability to accumulate high concentrations of heavy metals, *C. fluminea* are recommended by a number of studies as ideal species for biomonitoring purposes. The aim of this study was to determine the dose-response relationship of *C. fluminea* exposed to waterborne copper (Cu), which would enhance one's ability to design biomonitoring systems for continuous, *in situ* monitoring of Cu levels in water. Both valve closing and siphon extension were chosen as the behavioral endpoints in the present study. The ecotoxicological parameters of these two sub-lethal effects were estimated and compared to determine the sensitivity of both behavioral responses under Cu stress, a crucial metric when assessing the feasibility of such systems for biomonitoring within aquatic ecosystems. The improved valvometry technique allows tested bivalves with a free-range spontaneous situation to avoid stresses from experimental artefacts. We linked proposed valve daily rhythmic models and toxicodynamics-based Hill model to predict valve dynamic responses under different Cu exposures with a circadian valve rhythmic endpoint. We found Cu detection thresholds of 5.6 (95% CI: 2.1 – 9.3) and 19.5 (14.6 – 24.3) ug L^{-1} for response times of 300 and 30 min, respectively. We showed that when exposure Cu concentrations exceed 50 ug L^{-1}, the differential degree of valve rhythmic response has a noticeable sensing ability within 30 min. Our study implicates an early warning dynamic biomonitoring system that provides potential *in situ* detection of waterborne Cu by circadian valve activities in *C. fluminea*. We conclude that the proposed daily valve-rhythm model can be utilized to predict valve dynamic responses under different Cu-exposure concentrations, taking into account circadian valve-rhythm endpoints, while using a precise valvometry system to validate the simulation.

MO105
Why are mammalian focal species unaffected by chlorpyrifos applications? Integrating data on foraging-behaviour, exposure, and toxicokinetics
M. Foudoulakis, Dow Agrosciences / RSRA ERS; S. Norman, RidgewayEco; C. Wolf, B. Giessing, Tier3 Solutions GmbH; R. Dittrich, Tier3 Solutions GmbH / Wildlife Ecology; N.N. Poletika, Dow Agro Sciences LLC / Field Exposure and Effects Department; G. Weyman, ADAMA Agricultural Solutions Ltd.
Tier 1 wild mammal risk assessment indicates high risk from use of chlorpyrifos (CP) due to its high toxicity to mammals when tested in standard laboratory studies. However, when aiming to conduct a realistic risk assessment, it is important to understand the status and ecology of the mammalian community present in the target crop field. In this respect it is important to estimate basic population parameters of species breeding within the treated fields (long term survival and reproductive performance), their foraging behaviour and feeding ecology, and the spatial & temporal movement of the focal species to evaluate factors (both natural and anthropogenic) which may influence reproductive performance. In addition it is equally important to collect exposure and mechanistic data to support and help explain findings in the field. Several field studies have been conducted towards this aim. To gain information on the mammalian communities within the CP-treated fields a variety of methods were used depending on the goal of the study and the species in focus, which allows measurement and ranking of any factors influencing the local mammalian community, including the application of CP itself. The work undertaken over consecutive years gave a good insight into exposure of mammals utilizing treated fields/fruit orchards. In order to support field findings and provide a higher tier risk assessment for mammals, mechanistic information were also provided based on a body burden model describing Toxicokinetics (TK) and Toxicodynamics (TD). This presentation will describe the comprehensive and holistic approach which was followed, the new approaches for mammalian studies in risk assessment over consecutive years of data collection, and will explain why the high risk of mortality predicted by the Tier 1 risk assessment is not seen in the field.

Cost effective and ecological relevant approaches in environmental toxicology using invertebrate species (P)

MO106
Disruption of hypopharyngeal gland function in honey bees exposed to a dietary neonicotinoid (imidacloprid)
E. Collison, TSGE Consulting Ltd. / Biosciences College of Life and Environmental Sciences; H. Hird, Fera Science Ltd; C. Tyler, Biosciences College of Life and Environmental Sciences; J.E. Cresswell, The University of Exeter / Biosciences College of Life and Environmental Sciences
The neonicotinoid imidacloprid impairs development of the honey bee (*Apis mellifera*) hypopharyngeal gland (HPG), but whether HPG function is correspondingly disrupted has been untested, which undermines the ecological relevance of HPG-related assays in pesticide risk assessment. To determine whether imidacloprid indeed disrupts HPG function, we therefore implemented laboratory and field studies, using enzymatic, molecular and behavioural endpoints. Specifically, we investigated whether dietary exposure affected temporal polyethism, using Radio Frequency Identification (RFID) technology to track hive traffic in free-flying bees. In the laboratory, we investigated whether dietary exposure affected the enzyme systems that support larval nutrition (major royal jelly proteins, or MRJPs) and social immunity (glucose oxidase, or GOX). Overall, we demonstrate that dietary exposure of honey bees to neonicotinoid pesticide is potentially capable of causing generalised disruption of HPG function, which implies that imidacloprid-induced changes in HPG development can lead to detrimental effects on colony function. We believe this provides some overall support for the ecological relevance of HPG-related assays in pesticide risk assessment involving sublethal effects on honey bees. It is evident that further work is needed to test the field-relevance of some of our findings (namely imidacloprid-induced disruption to nutrition and social immunity), as in some cases (temporal polyethism) transcriptional responses that we observed did not translate into functionally significant impacts on bee health, highlighting the need to cross reference gene expression bioassays with ecologically relevant behaviour. Our work highlights the potential utility of new enzymatic, molecular and behavioural ecotoxicological endpoints for risk assessment of sublethal effects on honey bees, if further work can clarify their ecological relevance to colony-level impacts on bee health under more field realistic exposures.

MO107
Deciphering mechanisms of malathion toxicity under pulse exposure of the freshwater cladoceran Daphnia magna
L.N. Trac, Danish Technical University; O. Andersen, Roskilde University; A. Palmqvist, Roskilde University / Department of Environmental Social and Spatial Change
The organophosphate pesticide (OP) malathion is highly toxic to freshwater invertebrates including the cladoceran *Daphnia magna*, a widely used test organism in ecotoxicology. To assess whether toxic effects of malathion are primarily driven by exposure concentration or by exposure duration, *Daphnia magna* was pulse exposed to equivalent integrated doses (duration x concentration), i.e. 3h x 16 μg/L, 24h x 2 μg/L and 48h x 1 μg/L. Following recovery periods of 3h, 6h, 24h and 48h the toxicity of malathion on different biological levels in *Daphnia magna* was examined by analyzing the following endpoints: survival and immobilization; enzyme activities of Acetylcholinesterase (AChE), Carboxylesterase (CbE), and Glutathione S-transferase (GST); and Acetylcholinesterase gene expression at the transcriptional level measured by qPCR. The results showed no difference in survival among equivalent integrated doses. Adverse effects were driven by exposure concentration rather than duration. Specifically, short pulse exposure to high concentration of malathion (3h x 16 μg/L) resulted in more immobilized daphnids, lower AChE and CbE activities and higher transcript level of AChE gene compared to long pulse exposure to low concentration (48h x 1 μg/L). The expression of the AChE gene was up-regulated, indicating a compensatory mechanism to cope with inhibition of the enzyme. In addition, for this OP insecticide, the severity of the effects increased during the postexposure recovery period. The results of this study indicate that Environmental Risk Assessment based on the standard OECD immobilization test may underestimate OP risk in certain situations, and emphasize the relevance of employing a realistic exposure test scenario. The study has helped elucidate the response mechanism at the molecular level of the target enzyme for OP pesticides, which was still questionable in previous studies. More work on cytochrome P450 (CYP), CbE and GST regulation during and after exposure could further improve the understanding of molecular responses of these enzymes to toxicity of OPs in *Daphnia magna*.

MO108
Does long-term fungicide exposure affect the reproductive performance of leaf-shredders?
P.T. Baudy, University of Koblenz-Landau / Institute of Environmental Sciences; J. Zubrod, Institute for Environmental Sciences University of Koblenz-Landau / Institute for Environmental Sciences; M. Konschak, University Koblenz-Landau / Institute for Environmental Sciences; M. Weil, ECT Oekotoxikologie GmbH / Institute for Technology Assessment and System Analysis ITAS; R. Schulz, University of Koblenz-Landau / Institute for Environmental Sciences; M. Bundschuh, Department of Aquatic Sciences and Assessment Swedish University of Agricultural Sciences / Department of Aquatic Sciences and Assessment
Leaf-shredding amphipods play a critical role in the ecosystem function of leaf litter breakdown, a key process in detritus-based aquatic ecosystems. However, these organisms' fitness and functioning may be adversely influenced by exposures to fungicides, a group of pesticides targeting conserved sites of toxic action, while the effects on shredders' reproductive performance have not yet been assessed. To fill this knowledge gap, a semi-static 56-day partial life-cycle bioassay with *Hyalella azteca* (ten animals/replicate; *n*=30) was performed. Two field relevant levels of a fungicide mixture (at a low and a high sum concentration of 5 and 25 μg/L, respectively) were tested, whereby the single fungicide concentrations in the low sum concentration (1 μg/L each) corresponded approximately to the fungicides' regulatory acceptable concentrations (according to the European Union's environmental risk assessment; EU-ERA). Endpoints related to the energy processing (leaf consumption and feces production), the

growth, and the reproduction (amplexus pairs, number, and length of offspring) of the amphipods were assessed. While leaf consumption was unaffected, exposure to both fungicide treatments significantly reduced amphipods' feces production (~20%) compared to the control, which may be indicative for an increased food utilization to compensate for stress-related energy demands. However, this mechanism did not fully compensate for the higher energy demand and might have caused trade-offs in the energy allocation among physiological processes: while growth remained unaffected, amphipods forming amplexus were less abundant in both fungicide treatments (only significant in the high treatment). As a result, time to release of first offspring was delayed in both treatments and the number of offspring was significantly lower in the high treatment, whereas offspring length was unaffected. Moreover, a 5-10% increase in mortality was observed in both fungicide treatments compared to the control, which may suggest a reduced allocation of energy to maintenance. The results of this study indicate that chronic fungicide exposures can negatively impact shredders' reproductive performance. This may translate into lower abundances and thus a reduced contribution to leaf litter breakdown, which may have detrimental consequences for detritus-based food webs. Moreover, this study provides further proof that the EU-ERA procedures for fungicides may not safeguard aquatic ecosystems.

MO109

Using in-situ bioassays with the aquatic snail Physa acuta to assess impacts of wildfires on water quality

M.S. Oliveira, Biology; A. Ré, Aveiro University & CESAM / Biology; J. Puga, I. Campos, University of Aveiro / Department of Environment Centre for Environmental and Marine Studies CESAM; J.L. Pereira, University of Aveiro / Department of Biology Centre for Environmental and Marine Studies CESAM; J.J. Keizer, University of Aveiro / Department of Environment and Planning CESAM; F. Gonçalves, University of Aveiro / Department of Biology Centre for Environmental and Marine Studies CESAM; N. Abrantes, University of Aveiro / CESAMDAO

Wildfire is a common phenomenon in South-Europe, namely in Mediterranean countries as Portugal, where over the last decade an average of 144 000 ha burnt per year. It is known that wildfires affect aquatic systems altering both physical and chemical proprieties through the increased bioavailability and transportation of pyrolytic substances such as polycyclic aromatic hydrocarbons (PAHs) and metals associated to ash/soil loads. Hence, river ecosystems, particularly its biota, require a closer examination regarding wildfire effects. Once *in situ* assays address more realistic environmental multi-stress situations, an *in situ* bioassay at a Portuguese recent burned area (Miranda do Corvo, Coimbra) was performed to test reproductive effects by using the aquatic snail *Physa acuta*. Reproductive parameters, such as the total number of eggs, egg masses per snail, average of eggs per egg masses and the average of eggs and masses per snail were the end points tested at the end of the 8 days of exposure. The assay was performed at the time of the first major rainfall events and comprise four distinct sites: one reference site located in Ceira river upstream the burnt area (RUS); and three other sites, two of them located within the burnt area in tributary streams (SDS and SUS) and one downstream the burnt area in the Ceira river (RDS). Test chambers were elaborated accordingly to the needs of the pulmonate snail, allowing floatage and luminosity entrance. All the endpoints assessed indicate that RUS (the reference site located upstream the burnt area) was the site were reproduction was less affected, while SDS (a stream within the burnt area) was the site with lower reproductive outputs. Hence, *Physa acuta* reproductive assay demonstrate to be an effective and reliable test to discriminate among aquatic systems impacted by wildfires. Further studies, considering the embryo development should be also assessed.

MO110

Effects and biotransformation of the preservative methylisothiazolinone in the amphipod Hyalella azteca

L.L. Halle, Roskilde University / ENSPAC; A. Palmqvist, Roskilde University / Department of Environmental Social and Spatial Change

The preservatives methylisothiazolinone (MI) together with the trademark ‘Kathon CG’, comprised of methylchloroisothiazolinone (MCI) and MI in a 3:1 ratio, have been investigated extensively the past decade owing to an increase in allergic contact dermatitis. The preservatives are present in many products ranging from cosmetics and household products to water based paints, cooling tower water, industrial applications and toys, posing a possible risk of exposure in many aspects of life. MCI/MI have been used extensively and effectively as a preservative since the 1980s with a broad spectrum of activity against fungi, yeasts and bacteria at low concentrations. Since the millennium, MI has been used as an individual preservative alongside the MCI/MI mixture and other biocides and to some extent as a replacement of MCI/MI. The reason may be that MCI/MI is on the list of dangerous substances (i.e., R43/H317) and has to be declared when present in concentrations >15 ppm in cosmetics. No such requirements were present for MI up until 2005 where the maximum concentration in cosmetics were set at 100 ppm, a 25-fold increase from when it was in combination with MCI in the 3:1 ratio having a maximum concentration of 3.75 ppm. However, in 2015 EU declared a limit of 15 ppm MI in rinse-off cosmetics and no safe limit was specified for leave on cosmetics. In industrial products there is also a self-classification system with a limit of 0.1 % (1000 ppm), but it is not regulated as the self-classification name implies. Taking all of these sources into consideration the concentration of these compounds in water bodies may be higher than previously assumed and therefore pose a possible risk to the freshwater invertebrates living there. *Hyalella azteca* is an example of a well-distributed freshwater amphipod that is a well-established model organism in ecotoxicology. This study aims to investigate the effect of MI on *H. azteca*, as well as to explore MI biotransformation by *H. azteca*. Effects are assessed as changes in mobility and survival, and cellular reactions to reactive oxygen species (i.e., catalase induction, superoxide dismutase activity and lipid peroxidation) after MI exposure. Biotransformation is investigated by CYP induction and GST activity as well as disappearance rate with and without *H. azteca* present. Results from this ongoing study will be presented and discussed in relation to the current regulations.

MO111

Evaluation and improvements of a mayfly, Neocloeon (Centroptilum) triangulifer (Ephemeroptera: Baetidae) toxicity test method.

J.M. Lazorchak, U.S. EPA / Office of Research and Development; H. Haring, The McConnell Group; K. Wyatt, W. Thoeny, S. DeCelles, The McConnell Group c/o U.S. EPA Cincinnati; J. Miller, US Geological Survey; A. Dickinson, Illinois Natural History Survey; M. Raby, The University of Guelph; T.S. Schmidt, USGS / Water Resouces Div; D.J. Soucek, Illinois Natural History Survey / Illinois Natural History Survey; D. Walters, USGS / Fort Collins Science Center

A recently published test method for *Neocloeon triangulifer* assessedthe survival and growth of larval mayflies exposed to several reference toxicants (NaCl, KCl, and $CuSO_4$). Results were not able to be replicated in subsequent experiments. To identify potential sources of variability, the authors measured 7-day growth and survivorship in NaCl, using: (a) 1- vs. 3- vs. 5-day-old larvae, (b) 1-day-old larvae hatched from freshly collected eggs (not stored at cold temperatures) vs. eggs held in long-term storage at 4°C, and (c) 1-day-old larvae from five different laboratory cultures (two U.S. EPA, one USGS, one University of Illinois and one from University of Guelph). Fifty percent lethal concentration (LC50, mg/L) and 25% inhibition concentration (IC25, μm) point estimates were used to quantify survival and growth, respectively. Statistically significant differences in NaCl LC50s were observed among different ages of mayflies at test initiation (LC50=616.56, 989.43, 1667.24), with older organisms being less sensitive. No significant differences in growth could be elucidated between different aged treatments. Survival and growth of freshly collected eggs (LC50=701.27, IC25=626.56) differed significantly from eggs stored at 4°C for either three (LC50=394.13, IC25=424.47) or five (LC50=424.18, IC25=361.28) months, though no significant differences were observed between stored cohorts. A comparison of freshly collected eggs from 4 of the 5 different laboratory cultures tested do far showed no significant differences in survival or growth. Additional results will also be presented on larval age, storage, and laboratory source comparisons with KCl and CuSO4, and comparisons of freshly collected eggs vs 2 month old stored eggs at 10°C. To ensure consistent and sensitive test results we recommend continuing the use of 1-day-old larvae when using this species.

MO112

Toxic effects of wildfires on aquatic systems: in situ bioassays

A. Ré, Aveiro University & CESAM / Biology; M.S. Oliveira, Biology; J. Puga, I. Campos, University of Aveiro / Department of Environment Centre for Environmental and Marine Studies CESAM; J.J. Keizer, University of Aveiro / Department of Environment and Planning CESAM; J.L. Pereira, F. Gonçalves, University of Aveiro / Department of Biology Centre for Environmental and Marine Studies CESAM; N. Abrantes, University of Aveiro / CESAMDAO

Wildfires constitute a diffuse source of contamination of aquatic systems affecting water quality, through the production and transport of pyrolytic substances such as polycyclic aromatic hydrocarbons (PAHs) and metals associated to ash/soil loads. However, the effects of these compounds from recently burnt areas on the aquatic biota have been poorly studied. Hence, the objective of this study was to assess the ecotoxicological effects of wildfires in aquatic systems. A sampling area, recently burnt, was selected near Miranda do Corvo (Portugal). Five sites were selected: two in the main water course of the watershed - Ceira river, being one located upstream (RUS) and the other downstream (RDS) the burnt area ; two in tributary streams within the burnt area (SUS and SDS); and finally one in a stream at an unburned area (CS). During the first rainfall events after the wildfire, distinct groups of organisms, including the water flea *Daphnia magna*, the freshwater shrimp *Atyaephyra desmaresti* the freshwater clam *Corbicula fluminea* and the mosquitofish *Gambusia holbrooki* were exposed in situ, in all five sites, using test chambers. With exception of *D. magna*, all other tested organisms can be found in Ceira river. After an exposition period of four days, the mortality and post-exposure feeding inhibition were evaluated. Feeding depression after exposure time was selected as a sub-lethal endpoint because it is a quick, sensitive and ecologically relevant indicator of toxic stress. The results showed a very low mortality for all the species and sites, thus this lethal parameter was not sensitive to discern impacts among the assessed sites. Conversely, the sub-lethal post-exposure feeding inhibition endpoint, revealed a decrease of feeding rate, in streams within the burnt area (SUS and SDS), that seemed to be the most affected

places in the study area. The sites outside the burned area, both on river (RUS) and on the stream (CS), showed no adverse effects in this endpoint. Hence, the current results showed that *in situ* bioassays were a suitable tool to assess the risks of wildfire to aquatic species and that the post-fire runoff can sub-lethally impair the aquatic organisms in water bodies located within or downstream the burnt area.

MO113

Influence of surfactants in the bioaccumulation kinetics and metabolism of selected pharmaceuticals in benthic invertebrates

m.j. garcia, ISA / UMR Equipe Traces rue de la Doua Villeurbanne France; M. Sordet, A. Buleté, Institut des Sciences Analytiques / UMR Equipe Traces rue de la Doua Villeurbanne France; J. Garric, Irstea Lyon / Ecotoxicological Laboratory; E. Vulliet, Institut des Sciences Analytiques / UMR Equipe Traces rue de la Doua Villeurbanne France

Nowadays, it has been widely demonstrated that elimination of many pharmaceuticals during conventional wastewater treatment is incomplete. Therefore, despite at low concentrations, these bioactive compounds are being discharged in natural waters on a regular basis and are consequently considered as semi-persistent contaminants[a]. The structural and functional equilibrium of freshwater ecosystems could be compromised by their environmental presence. However, data on this regard is still insufficient for a full risk assessment, particularly on their direct or indirect effects in the first trophic levels. Surfactants, on the other hand, are used in much higher quantities and also released into sewage systems or directly in surface waters. Their environmental presence and potential ecotoxicity have been thoroughly studied[b]. Benthic invertebrates are key in the functioning of aquatic ecosystems, as they are involved in nutrient recycling and represent a relevant food source for other invertebrates and fish[c]. The amphipod *Gammarus fossarum* is frequently used as sentinel species of water quality, as it is widespread in western Europe and its physiology is well known. Recent works have shown the bioaccumulation of selected pharmaceuticals in gammarids[d,e], but have not fully addressed either their bioaccumulation kinetics or their capacity to metabolize the toxicant. The main goal of this work is to study the role of a mixture of frequently detected detergents in the bioaccumulation kinetics of selected pharmaceuticals in *G. fossarum*, evaluating their potential synergetic or antagonistic effects. Laboratory exposure experiments for both pharmaceuticals and detergents (concentration ratio 1/25) were set up for three individual compounds: the anxiolitic oxazepam, the anti-inflammatory ibuprofen and the antibiotic sulfamethoxazole. The feeding rate was selected as end-point of the experiment. Gammarids samples were processed using microQuEChers extraction and pharmaceuticals bioaccumulation and metabolism was followed-up by means of nanoliquid chromatography coupled to MS/MS (nanoLC-MS/MS) and high resolution mass spectrometry (nanoLC-HRMS), aiming to elucidate potential transformation products. MO114

Eliminating Stressors in Laboratory Tests with Chaoboridae and Corixidae

F. Joyce, S. Taylor, Cambridge Environmental Assessments

The sensitivity of organisms tested under laboratory conditions may differ significantly to those exposed to contaminants in their natural environment. Standard procedures for laboratory invertebrate bioassays operate under optimal laboratory conditions specified in OECD guidelines, which are generally ‘sterile’, e.g. void of natural refugia and food. However, when using feral organisms, the change from field to laboratory conditions can cause additional stress, thus potentially affecting the outcome of acute toxicity tests for use in regulatory risk assessments of plant protection products. The need for test modifications for some taxa based on individual species life-histories and habitat preferences are important to consider for successful testing of non-standard invertebrates. For example, the acclimatisation period and testing conditions in the laboratory can be modified depending on the requirements of different species in their natural environment and their response to stressors such as light levels and temperature. Here we will present examples taken from two invertebrate taxa (Chaoboridae and Corixidae) for which control mortality during acute toxicity tests performed by Cambridge Environmental Assessments was anomalously high in comparison to standard organisms. We will discuss the subsequent research and trials carried out to mitigate non-chemical stress and increase control survival and reliability, and also provide recommendations for the potential development of standard operating procedures for non-standard invertebrate work.

MO115

Culturing and Testing Early Life-History Stage Larvae of Chaoborus crystallinus and Cloeon dipterum

M. Allen, S. Taylor, A. Howells, F. Joyce, F. Radford, Cambridge Environmental Assessments

The juvenile stage of freshwater invertebrates are regarded as the most sensitive life-history stage to the toxic effects of exposure to Plant Protection Products (PPPs). Standard invertebrate testing approaches e.g. *Daphnia Magna*(OECD 202), Chironomid (OECD 235) use Here we will present the results of the development of testing approaches for two non-standard invertebrates, the mayfly (*Cloeon dipterum*) and the phantom midge (*Chaoborus crystallinus*) using specific life stages. Organisms were collected from outdoor mesocosms at Cambridge Environmental Assessments (CEA) and cultured in the laboratory. Mayfly and *Chaoborus* cultures were maintained in the laboratory within mesh cages so that adults would emerge and re-lay their offspring within the cultures. As this method was unsuccessful we attempted a range of alternatives to breed these species under controlled conditions. For example, beakers of de-ionised water were added to the *Chaoborus* culture cages and a period of low light at dawn and dusk was introduced to encourage oviposition for both species. This proved temporarily successful for *Chaoborus*, however continued breeding did not occur. Mayflies failed to breed under the different conditions. In order to standardise our higher tier tests, larval stages 1 and 2 for mayflies were identified and *Chaoborus* within the size range 5-10 mm were used within the acute toxicity test. Although the results of this work did not meet the objectives that we set out to achieve (i.e. organisms of a known age were not able to be used), this presentation will show our experiences and also recommend next steps for further refinement of culturing and testing methods.

MO116

Magnetic particles' effects on survival and hatching of the rotifer Brachionus calyciflorus and the growth of the Chlorella sp. alga.

M.. Salcedo, I. De Vicente Ãlvarez-Manzaneda, University of Granada / Ecology

The main objective of this research is to study the possible toxicological effects of iron magnetic microparticles on the rotifer *Brachionus calyciflorus* and the cloroficean alga *Chlorella* sp. These magnetic microparticles have recently been proposed for the restoration of eutrophic aquatic ecosystem, for remove the phosphorus located in them. With the aim of carrying out the toxicological test on *B. calyciflorus*, it was followed ASTM protocol. During 24 hours the organisms were in contact with different concentrations of magnetic particles, analyzing the mortality of the organisms. On the other hand, a test about the rotiferb_s eggs hatching in contact with dissolved iron from the particles was carried out. In the case of the test with the alga *Chlorella* sp., OECD’s standardized protocol was followed. This test last 72 hours and they were used different concentrations of magnetic particles, after these 72 hours the inhibition growth of the alga was calculated. The results obtained were a CE50 of 1.63 g/l of iron for the rotifers and 0.085 g/l for *Chlorella* sp., the alga was more sensitive to the particles than planktonic organism being 100% of algal growth inhibition from 0.5 g/l. Hatching of *Brachionus calyciflorus* eggs in contact with the dissolved iron was total.

MO117

Effects of Chernobyl-derived radionuclides on fluctuating asymmetry and fecundity in Asellus aquaticus: 30 years on

N. Fuller, University of Portsmouth / Biology; J.T. Smith, University of Portsmouth / School of Earth and Environmental Sciences; A. Ford, University of Portsmouth / Biological Sciences

The effects of long-term, environmentally relevant doses of radiation on biota remain unclear owing to a lack of studies following chronic exposure in contaminated environments. Such studies are necessary to elucidate and mitigate the impacts of both planned and accidental releases of anthropogenic radioactivity on the environment. This field study aimed to determine the effects of chronic exposure to environmental radioactivity on an aquatic isopod, *Asellus aquaticus* using two cost effective biomarkers, fluctuating asymmetry and fecundity. Fluctuating asymmetry is defined as random deviations from the expected perfect bilateral symmetry of an organism and has gained prominence as an indicator of developmental stability in both ecotoxicological and ecological studies. *Asellus aquaticus* is a benthic detritivore commonly used in ecotoxicity testing of sediment-borne contaminants. Specimens were collected from littoral zones of six lakes with varying degrees of contamination from the Chernobyl incident in Belarus and Ukraine. Estimates of external dose rates at sample sites ranged from 0.01 to 35.9 $\mu Gy/hr^{-1}$ Levels of asymmetry were assessed using five independent traits measured using ImageJ. Mean brood size, weight of broods and brood sizes normalised to maternal weight were used to assess reproductive output at sites. A two-way ANOVA revealed significant differences in pooled levels of mean asymmetry between sites. However, there was no correlation of asymmetry with estimated external doses suggesting that differences in asymmetry were not attributed to radionuclide contamination. Further, no significant differences in weight-normalised brood sizes and weights were exhibited between asellids collected from sites along the contamination gradient. All brood sizes and weights of Chernobyl asellids were within the range of reference sites. These results indicate that following 30 generations of radiation exposure, there are no detectable effects on developmental stability and reproduction in asellid populations. Studies are ongoing to determine the genetic variability and potential adaptation of these invertebrates to provide protection from ionising radiation. These will findings enhance our understanding of the response of biota to chronic pollutant exposure and will help elucidate long term effects of large scale nuclear incidents such as Chernobyl and Fukushima.

MO118

Culturing and Testing Early Life-History Stage Larvae of Asellus, Crangonyx, Lymnaea

F. Pickering, S. Taylor, A. Howells, F. Radford, Cambridge Environmental Assessments

The conduct of acute aquatic toxicity testing in the laboratory provides an efficient means of predicting the effects chemicals may have in the environment. Standard invertebrate testing approaches use age specific organisms e.g. Daphnia magna (OECD 202, 2004) and Chironomid (OECD 235, 2011) to eliminate potential differences in sensitivity at varying life-stages. However, there is an increasing need for the development of standard culturing and age recommendations for non-standard invertebrates used in higher-tier toxicity testing. We will present the results of recent work carried out by Cambridge Environmental Assessments (CEA) in this area for culturing age specific non-standard invertebrate species for use in acute laboratory studies. A range of freshwater species were selected for age specific culturing and testing namely: *Lymnaea stagnalis*, *Crangonyx pseudogracilis*, and *Asellus aquaticus*. Organisms were collected from outdoor mesocosms and bred in the laboratory and juveniles produced were isolated periodically to ensure age specific juveniles for testing. We present the methods used for collecting, acclimating and culturing these freshwater invertebrates and also make recommendations based on the suitability of organisms selected and recommend ages for use in testing. In addition, we will highlight the need for any further research and development required.

MO119

Rediscovering a simple and precise methodology to assess filtering rate quantification for bivalve: Neutral red dye

M. Martinez-Haro, IREC-Instituto de Investigaci6n en Recursos Cinegéticos / Department of Life Sciences; A.J. Pais-Costa, T. Verdelhos, MARE; J.C. Marques, IMAR-Institute of Marine Research, Department of Life Sciences, University of Coimbra / Department of Life Sciences; P. Acevedo, Instituto de Investigacion en Recursos Cinegeticos / SaBio IREC

Neutral red is a weakly cationic dye soluble in water, with a low toxicity for almost all class of organisms, for which has been used as histological and vital stain since early twentieth century. Estimating the amount of water filtered by bivalves is one of the earliest applications of neutral red. However we found less than twenty studies applying this methodology since its description in 1954. The aim of our study was to optimize the methodology of filtering rate based on the solution of neutral red by addressing the effect of i) acidifying pH; ii) holding temperature before spectrophotometric reading; and time iii) before and iv) after acidification of solutions of neutral red used for filtering assays. Furthermore, as a case study we fine-tuned the filtering assay for the estuarine bivalve, *Cerastoderma edule*, as potential species to be used for estuarine monitoring purposes. Results showed not statistically differences in absorbance of neutral red solutions holding at 4 or 20ºC, neither in solution acidified between the range of pH 4-5. However, absorbance at 545 nm decreased significantly as pH of solutions increase at pH 6. The time before acidification has not a significant effect on absorbance. However, once the neutral red solution is acidified, the absorbance of the solution tends to decrease over time for which is recommended read the absorbance in the first 24h. Finally, our results showed that the sensibility of this technique decrease at low concentrations, for which is recommended used neutral red concentration enough to allow, after the filtering period, final concentrations above 0.5 mg/L. For *C. edule* the filtering conditions per individual were optimized as 100 ml of 4 mg/L of neutral red dye during 30 min period in dark conditions. The Cd 48-h EC50 postexposure filtering for *C. edule* was 3.4 folder lower than the 48-h LC50 (0.33 vs 1.13 mg/L, respectively), confirming filtering rate as a more sensitive and cost-effective endpoint for this bivalve than mortality. The bioassay using the bivalve *C. edule* based on postexposure filtering rate based on this simple colorimetric technique appears to have potential as a tool for environmental estuarine assessment. Future development of field assays based on postexposure filtering rate (namely, in situ assays) with this species is promising to use in monitoring programmes. We expect that the new harmonized protocol became in a widely used cost-effective tool for monitoring filtering rates.

Earthworms (Eisenia fetida) response to short-term exposure to triclosan

J. Zaltauskaite, Vytautas Magnus University / Department of Enviromental Sciences; D. Miskelyte, Vytautas Magnus University / Department of Environmental Sciences

Triclosan (TCS) is a broad-spectrum antimicrobial and antifungal agent and it is a common constituent of household and personal care products. TCS widespread use has resulted in its introduction into environment and has raised concerns regarding possible adverse effects on terrestrial and aquatic organisms. Earthworms *Eisenia fetida* were exposed to 10-750 mg/kg of triclosan for 14 days. Mortality and biochemical responses including the activity of catalase (CAT), superoxide dismutase (SOD), glutathione reductase (GR) and malondialdehyde (MDA) were examined after 4, 7 and 14 days. None of the tested TCS concentrations evoke earthworm mortality during the experiment. Triclosan exposure reduced the growth of earthworms. Short time exposure (up to 14 days) showed, that highest activity of catalase was observed after 4 days exposure and by increasing TCS exposure time catalase activity was dereasing. Highest superoxide dismutase and glutathione reductase activity was detected after 7 days exposure of triclosan.

MO121

Passive dosing of hydrophobic organic chemicals in toxicity tests with Caenorhabditis elegans

F.C. Fischer, Hemholtz Centre for Environmental Research - UFZ / Cell Toxicology; L. Böhm, Justus Liebig University Giessen / Institute of Soil Science and Soil Conservation; C. Möhlenkamp, Federal Institute of Hydrology / Department Biochemistry and Ecotoxicology; S. Höss, Ecossa; E. Claus, Federal Institute of Hydrology / Department Biochemistry and Ecotoxicology; R. Düring, Justus Liebig University Giessen / Institute of Soil Science and Soil Conservation; S. Schaefer, Federal Institute of Hydrology / Biochemistry Ecotoxicology

The standardized toxicity test with the nematode *Caenorhabditis elegans* (ISO 10872) is widely used for toxicity testing of chemicals. Chronic toxicity endpoints such as reproduction are thereby preferably assessed because of their higher sensitivity and ecological relevance compared to acute mortality. Due to its simple, cost-efficient cultivation and short generation time, *C. elegans* is particularly suitable for high-throughput toxicity testing. Testing sub-lethal parameters such as reproduction requires feeding with *Escherichia coli* cells during the test. However, the bacteria can act as sorptive sink and, therefore, reduce the freely dissolved, bioeffective concentration (C_{free}) of hydrophobic organic chemicals (HOCs). This results in poorly defined exposure conditions and reduced test sensitivity when actively spiking the HOCs into the test medium by using an organic solvent as solubilizing agent. Passive dosing is a promising technique for controlling and maintaining constant C_{free} in small-scaled toxicity tests since potential decreases of C_{free} are compensated by continuous partitioning of chemicals from a saturated reservoir. This study investigated the applicability of passive dosing of HOCs from silicone O-rings in the chronic *C. elegans* toxicity test. 10 polycyclic aromatic hydrocarbons (PAHs) that cover a broad range of hydrophobicity were tested as model chemicals. During all experiments, C_{free} of test chemicals was quantified by solid-phase microextraction (SPME), either in test medium or via headspace. Studies on release kinetics of test chemicals revealed that after preincubating the silicone O-ring in the test medium for 24 hours at 60 rounds per minute most PAHs reached equilibrium partitioning. During the 96 hours of *C. elegans* toxicity test, C_{free} of PAHs remained constant when applied by passive dosing, whereas C_{free} decreased by ≥ 90% until the end of the test when actively spiking the PAHs. This yielded in considerably lower EC_{50} values when exposing *C. elegans* by passive dosing compared to active spiking. As expected, neither C_{free} nor toxicity of PAHs decreased with increasing *E. coli* cell densities in test media when applying PAHs by passive dosing. In summary, passive dosing is a promising tool for assessing the chronic toxicity of HOCs with *C. elegans* whereby SPME proved to be suitable for verifying C_{free}.

MO122

A decade of progress on freshwater mussel toxicity testing and opportunities for further advancement

T. Augspurger, U.S. Fish and Wildlife Service / Ecological Services; N. Wang, USGS / Columbia Environmental Research Center; C.G. Ingersoll, U.S. Geological Survey / Columbia Environmental Research Center; W. Cope, North Carolina State University / Applied Ecology; C. Barnhart, Missouri State University / Biology

Freshwater mussels belonging to the family Unionidae include more than 670 species of bivalves worldwide. Many of these taxa are imperiled globally and IUCN lists 28 as extinct and 106 as endangered or critically endangered. Effects of toxicants are reasonable hypotheses to test as limiting factors because aspects of mussel life history make them vulnerable to degraded water or sediment quality. Juvenile and adult mussels are benthic suspension and deposit feeders exposed to pollutants in surface water, sediment, and pore water and through ingestion of filtered particles with sorbed contaminants. Mussel toxicology has advanced since the 2006 ASTM International *Standard Guide for Conducting Laboratory Toxicity Tests with Freshwater Mussels (E1706)* provided a foundation for evaluating the quality of toxicity tests conducted with early life stages of mussels to dozens of chemicals. Mussels are known to be sensitive (relative to other freshwater organisms) to ammonia, some metals and ions including copper, nickel, lead, zinc, chloride, sulfate, and potassium. However, the science lacks full identification of pollutants that may limit survival, growth, reproduction, behavior, recruitment and recovery of mussels because few of the potential causative chemicals have been evaluated in the laboratory. Also, toxicity tests seldom address mussel reproduction or recruitment with test durations short (e.g., typically 1- to 28-d) relative to mussel lifespans (e.g., typically 10- to 60-y). Advances in mussel feeding and husbandry have promise for conducting longer-term exposures evaluating growth and behavior. Developing standard methods for sediment toxicity testing and effluent toxicity testing with mussels may advance the field, as the water-only ASTM guideline did a decade ago. The vast majority of mussel species remain untested, and interspecies variability in chemical sensitivity has been examined and modeled, but not explained through mechanistic and or genomics approaches for informed species-selection in toxicity testing or risk assessments of untested species. To aid habitat evaluation, studies are needed to better characterize exposure (including sediment, pore water, and food influences) and to provide benchmarks to define acceptable pollutant concentrations in water, sediment, and diets. Field confirmation of benchmarks predicted by laboratory toxicity tests is important in determining the significance of pollutants and in design of ameliorative measures.

MO123

Comparing Single species Toxicity Tests to Mesocosm Community-Level Responses to Total Dissolved Solids Comprised of Different Major Ions.

J.M. Lazorchak, U.S. EPA / Office of Research and Development; C.T. Nietch, U.S. EPA / Water Supply Water Resources Division; B. Johnson, US EPA / Ecological Exposure Research Division; B. Ramakrishnan, U.S. Bureau of Reclamation; P. Weaver, U.S. EPA; D. Macke, U.S. EPA Test & Evaluation Facility / Office of Research and Development; K. Daniels, US EPA / Water Supply and Water Resources Div; S. DeCelles, The McConnell Group / co US EPA Cincinnati; D. Brown, U.S. EPA Cincinnati; H. Haring, The McConnell Group; K. Wyatt, The McConnell Group co US EPA Cincinnati; C.A. Impellitteri, US EPA / Water Supply and Water Resources Division

Total Dissolved Solids (TDS) dosing studies representing different sources of ions were conducted from 2011-2015. Emergence responses in stream mesocosms were compared to single-species exposures using a whole effluent testing (WET) format and an *ex-situ* method (single species tests in containers receiving mesocosm water). The first 4 years used a dose-response design for each year's TDS recipe, which differed based on the relative dominance of major ions. The 2015 experiment tested three of the previous year's recipes dosed simultaneously but at only one level of moderate specific conductivity (ca. 850 uS/cm). A mayfly, *Neocloeon triangulifer,* was incorporated for testing alongside the standard WET test organisms. Overall, *N. triangulifer* tended to be more sensitive than other standard test organisms, but there were differences in sensitivity between the *ex-situ* method and WET tests. *N. triangulifer's* sensitivity in the *ex-situ* exposure reflected that of mayfly emergence from the mesocosms. Caddisfly emergence was generally as sensitive to TDS exposures as mayflies in 2011-2014 tests, although less sensitive when the excess TDS was dominated by Cl^- salts. However, caddisfly emergence was not significantly different from the controls and therefore, not as sensitive as mayfly emergence for the 2015 constant conductivity study. Chironomids were less sensitive to excess TDS than Ephemeroptera and Trichoptera taxa when TDS was dominated by Cl^- and $NaHCO_3$, but appeared more sensitive when the TDS was a mixture of SO_4^{2-} and HCO_3^-. Mayfly emergence was the only emergence endpoint that demonstrated a clear and consistent adverse response to excess TDS. Emergence in the control was always the highest and sulfate the lowest. Cl^- and HCO_3^- were intermediate and similar in response, but overall significantly lower than the control. In the WET format, mayfly growth in bench tests was: control > Cl^- = SO_4 > HCO_3^-. For the 2015 experiment, where Cl^-, HCO_3^-, and SO_4 were adjusted to establish a conductivity of approximately 850 *u*S/cm, the 20% hazardous concentration (HC20) indicated that deleterious effects to mayflies occurred at this conductivity regardless of ion composition. These results suggest that stream benthic communities are significantly more sensitive to excess TDS from coal mining activities that leave leachable spoils rich in carbonate and sulfate than to produced waters emanating from deep oil and gas wells that tend to be dominated by sodium and calcium chloride.

MO124

Comparative toxicity assessment of lead on two Daphnid species

G. Araujo, Universidade de Aveiro / Biologia; C. Pinheiro, Department of Biology; A.M. Soares, Universidade de Aveiro / Department of Biology and CESAM; D. Abessa, Unesp / Marine Biology and Coastal Management; S. Loureiro, Universidade de Aveiro / Biology

Water is an essential resource for humans, economy and ecosystems and often can be under risk of contamination. Chemical contamination of anthropogenic source is generally related to industry, agriculture and urban activities. Lead is a naturally occurring metal, but high levels can be found in the environment due to antropogenic actions. Thereby, this study aimed to compare the toxicity of lead to two different Daphnid species, *Daphnia magna* and *Daphnia similis*, which are species from different climate scenarios. To accomplish this goal three toxicity tests were performed with both species. To predict the letal concentration (LC) of lead to these organisms an acute immobilisation test (OECD 201) was carried out. Regarding sublethal effects, Pb effects on the reproductive output and female growth was achieved through the reproduction tests (OECD 211). In addition, and looking at one of the functional traits of daphnids as filter feeders, feeding inhibition tests were carried out based on the protocol developed by McWilliam & Baird (2002). Comparing lethal concentrations for *D. magna* and *D. similis* it is noteworthy that the $LC_{50\text{-}48h}$ values were similar, with *D. magna* showing a slightly higher value ($LC_{50\text{-}48h} \cong 0.45$mg/l) than *D. similis* ($LC_{50\text{-}48h} \cong 0.36$mg/l). Regarding the chronic assay, *D. magna* was more influenced by Pb on the reproductive output and *D. similis* on growth. A similar pattern was also attained in the feeding inhibition tests. According to the obtained results we can see that Pb affects both daphinids in different ways, as also shown for other chemical compounds.

MO125

The application of the Weight of Evidence Approach as an integrative tool for ecotoxicological risk assessment in Iberian rivers

N. De Castro-Català, Universitat de Barcelona / Ecology; M. Kuzmanovic, CSIC Spanish National Research Council; A. Ginebreda, CSIC - Spanish National Research Council / Department of Enviromental Sciences; C. Barata, CSIC / Environmental Chemistry; I. Muñoz, University of Barcelona / Ecology

Chemical pollution is one of the most important threats to aquatic systems. The diversity of compounds present in these systems and the dynamics and interaction of these compounds with physical (water, sediment) and biological (amphibian, fish, invertebrate, algae) compartments make difficult to analyze the effects and to give solutions for appropriate management. European directives propose the use of different quality indicators to evaluate the environmental status of aquatic ecosystems and recommend combining chemical and biological analyses to determine the final quality status and facilitate interpretation of the results. Therefore, we adopted a "Weight of Evidence" approach (WoE) to perform a toxicological risk assessment of four threatened rivers of the Iberian Peninsula: the Ebro, the Llobregat, the Júcar and the Guadalquivir. The study comprised chemical and ecotoxicological information, gathered within the context of the SCARCE project. The lines of evidence (LoEs) included in this study were: ? Chemistry: included chemical data (emerging contaminants and priority substances –PS–) from both sediment and water compartments ? Toxicology: included three different sub-lethal toxicity tests (*Physella acuta* in situ reproduction test, *Daphnia magna* in situ feeding test, *Chironomus riparius* sediment exposure test) and also sediment Toxic Units (TUs) for *Daphnia magna* ? Ecology: included invertebrate benthic community richness and percentage of Tr. Chironomini and Oligochaeta (considered pollution-tolerant species) The general picture obtained from this risk assessment showed that the invertebrate communities of the four studied rivers were seriously affected by chemical pollution. Of the 20 sites studied, 17 presented a bad ecotoxicological status (Ecology and Toxicology LoEs) and only 2 sites of the Júcar presented a good ecotoxicological status. Among the PSs, we identified PFOS, organophosphorus pesticides (mainly chlorpyrifos), alkylphenols (mainly nonylphenol) and different metals (e.g. Ni, Pb) as the main specific drivers of the risk in most of the sites. The chemical and ecotoxicological LoEs gave complementary results, providing evidence on the need to include a set of different criteria to assess causality for a correct ecotoxicological risk assessment.

MO126

Effects of Copper-Chromium-Borate wood preservative at different level of biological organization of the earthworm E. andrei

S. Campiche, M. Visse, E. Grand, Swiss Centre for Applied Ecotoxicology; I. Werner, Swiss Centre for Applied Ecotoxicology / Department of Anatomy Physiology and Cell Biology; B. Ferrari, Ecotox Centre CH

Earthworms are commonly used organisms in ecotoxicology to assess soil quality or effect of chemicals on the soil fauna. In this study, the effects of a biocide, used for outdoor wood preservation and containing a mix of chromium, copper and borate (CuCrB), were evaluated at different levels of biological organization using the earthworm *Eisenia andrei*. Reproduction and behavioral endpoints were assessed using standardized ecotoxicological tests. Additionally and considering the important role earthworms play in organic matter breakdown, functional impacts were evaluated by measuring the feeding activity of the earthworms exposed to the biocide. For this purpose, the usefulness and feasibility of using the bait lamina method, which measure the disappearance of a series of organic bait ("bait") embedded in small PVC sticks inserted vertically into the soil, was investigated in a short (48h) and simple test under laboratory condition. Finally, the impact of the biocide was assessed at the molecular level, looking at metallothionein (mt), phytochelatin synthase (pcs) and cytochrome c oxydase 3 (cox3) gene expression after 48 hours and 28 days of exposure. Exposure to the CuCrB wood preservative affected the earthworm feeding activity and behavior to a greater extent than reproduction. An induction of the pcs gene was observed after 48h whereas is expression was stable after 28 days of exposure. The mt gene expression however was stable after 48h but was induced after 28 days of exposure. The respiratory chain seems to be affected in the presence of the biocide as the cox3 gene was repressed in exposed earthworms. These combined approaches allowed to assess the effects of pollutants from molecular to functional levels, bringing to light different impacted functions in the CuCrB exposed earthworms. Moreover, the use of the bait lamina test to assess the feeding activity of earthworms is a relatively simple laboratory method that allows the rapid screening of soil samples for sublethal effects due to the impact of chemicals, and also an assessment of the functional aspect of soils under standardized conditions. This approach shows promise for the a priori ecological risk assessment of chemicals.

MO127

Planarians in ecotoxicology: Effects of phenanthrene on Dugesia tigrina

F. Simão, Aveiro University & CESAM; C. Gravato, A.M. Soares, Universidade de Aveiro / Department of Biology and CESAM; J. Pestana, CESAM & University of Aveiro / Department of Biology and CESAM

Freshwater planarians are animal models for developmental and regeneration research and are being rediscovered as useful animals in neuropharmacology and

ecotoxicology. Such interest is based on their unique characteristics, such as a stem cell population that originates all other cell types and provides them with the ability to regenerate complete body parts including their nervous system which has similarities to that of vertebrates. Furthermore, a plethora of endpoints can be easily measured and quantified in these flatworms, including behavioral, regeneration, reproduction and biochemical parameters. Therefore, planarians have the potential to provide new insights on the effects of some well-studied and ubiquitous compounds, such as polycyclic aromatic hydrocarbons (PAHs). The sexual planarian *Dugesia tigrina,* a common freshwater predator, was used to study the effects of phenanthrene. The estimated 96-hour LC_{50} for phenanthrene was 830.62 µg/L, while acute EC_{50} for head loss was 483.06 µg/L. Sub-lethal endpoints such as locomotion, feeding and regeneration were measured over 8-day chronic exposures. After 8 days, behavior of animals exposed to the highest phenanthrene concentrations was affected, with exposed animals travelling smaller distances and showing toxic anorexia in comparison to controls. This study provides new data on the toxicity of phenanthrene to invertebrates, showing that exposure to this PAH can result in adverse effects to *D. tigrina* well below the concentration needed to induce mortality.

MO128

The effects of DEHP, an endocrine disrupting chemical (EDC), on the Egyptian cotton leafworm, Spodoptera littoralis

A. Aviles, University Pierre et Marie Curie / Department of Sensory Ecology; M. Maïbèche, Universite Pierre et Marie Curie / Department of Sensory Ecology; I. Boulogne, Universite Pierre et Marie Curie / Département dEcologie Sensorielle; D. Siaussat, Universite Pierre et Marie Curie / Department of Sensory Ecology

Di-(2-ethylhexyl)-phthalate (DEHP)[1] is a plasticizer widely used in plastics to increase flexibility and known to have endocrine disrupting effects on vertebrate species. Endocrine disrupting chemicals (EDC) are pollutants which can alter the health of an organism, its progeny or even a (sub)population, by interacting with the hormonal system. In the frame of the ANR DISCO project (endocrine Disruption of Insect Sexual COmmunication), the current project focuses on the effects of DEHP on a crop pest: the Egyptian cotton leafworm. As EDCs are known to have major effects during early development and the development of reproductive tracts, we first investigated the effects of DEHP on the post-embryonic development (length and number of larval instars, larval weight and food consumption) and the sex ratio of *S. littoralis*. To study the effect of DEHP at population scale, we then focused on its effect on the female sex pheromone detection by males. Indeed, this crucial process for mating is under endocrine control in our species[2] and could be potentially disrupted by DEHP. Besides, we investigated the potential modifications in the ecdysteroid titration in the hemolymph of larvae and adult males, using Enzyme Immuno Assay (EIA)[3]. For both those experiments, we chose to feed larvae, from the end of the 2nd larval instar to the last larval instar with either food with ethanol (control) or contaminated food at several concentrations (from 10pg to 40mg DEHP per gram of food). Most of the experiments are still in progress. Preliminary results showed that DEHP is weakly toxic for *S. littoralis*. Mortality is increased only for the two highest concentrations. DEHP would reduce the percentage of males at 1ng DEHP per gram of food and some effects on larval growth rate were recorded and have to be confirmed in additional experiments. [1] European Chemical Agency – ECHA (2008). European Union Risk Assessment Report – bis(2-ethylhexyl) phthalate (DEHP). JRC45705. ISSN: 1018-5593. [2] Bigot Laetitia, Abdul Shaik Haq, Bozzolan Françoise, Party Virginie, Lucas Philippe, Debernard Stéphane, Siaussat David (2012). Peripheral regulation by ecdysteroids of olfactory responsiveness in male Egyptian cotton leaf worms, *Spodoptora littoralis*. Insect Biochemistry and Molecular Biology. 42:22-31. [3] Porcheron, P., Morinière, M., Grassi., J., Pradelles, P. (1989). Development of an enzyme immunoassay for ecdysteroids using acetylcholinesterase as label. Insect Biochemistry. 19:117-122.

MO129

The effects of sublethal doses of pollutants on crop pest, Spodoptera littoralis

D. SIAUSSAT, Institute of Ecology and Environmental Sciences / Department of Sensory Ecology

Pesticides have long been used as the main solution to limit agricultural pests but their widespread use resulted in chronic or diffuse environmental pollutions, development of insect resistances and biodiversity reduction. The effects of low residual doses of these chemical products on organisms that affect both targeted species (crop pests) but also beneficial insects became a major concern, particularly because low doses of pesticides can induce various effects. In addition to the negative effects, some studies highlighted unexpected positive - also called hormetic - effects on insects, leading to surges in pest population growth at greater rate than what would have been observed without pesticide application. The present study aimed to examine the effects of sublethal doses of various representative products of large pesticide families used against a major pest insect, the cotton leafworm Spodoptera littoralis, and known to present a residual activity and persistence in the environment. Using an integrated approach from genes to behavior, we studied the impact on the peripheral olfactory system and the sexual or feeding behavior of our crop pest model following application of sublethal doses of deltamethrin, methomyl and chlorpyrifos. Whereas sublethal doses of methomyl appeared to disrupt the feeding behavior of larvae, we demonstrated a hormetic response of males to sublethal dose of deltamethrin. We completed our study by molecular (qPCR), biochemical (proteomic, AChE activity and metabolic) and electrophysiological approaches in order to decrypt the involved mechanism in pesticide response as well as in the behavioral disruption.

Fate, Effects and Risk Assessment of Chemicals in Aquatic and Terrestrial plants (P)

MO130

A novel flow-through system adapted from OECD 201 test to assess algae toxicity for difficult substances

D. Lejon, A. Bellemain, M. Bayle, Rovaltain Research Company; P. Bicherel, P. Thomas, KREATiS

The OCDE 201 algal test is historically performed in static conditions where media are not renewed during the 72h exposure. Even if this method is sufficient for chemicals which are stable in water, this is often not the case for substances which degrade either abiotically (due to hydrolysis or volatilisation) or biotically (due to biodegradation or algal metabolism). For such substances, toxicity to algae is more difficult to determine due to probable difficulties in maintaining substance concentrations throughout the test. In order to generate high quality toxicity results where the substance was present throughout the test, Rovaltain Research Company has developed an innovative dynamic test system, where algae are exposed to a constant concentration of chemical over the entire test period. This work has been carried out as a part of the DAMIER project, a French funded project for the development and the use of High Accuracy QSAR models for REACH compliance. Indeed high quality data provided by this new method have been used to validate toxicity predictions of High Accuracy QSARs (HA-QSARs). After having designed and developed the experimental device (an "algaestat"), preliminary tests using a range of chemical substances known for their instability (volatility, photosensitivity,…) provided encouraging results. These preliminary results confirm the relevance of such flow-through systems to obtain high quality toxicity data for substances which are less stable under OECD 201 test conditions.

MO131

An efficient bioassay using Chlorococcum infusionum in soil media

S. Nam, Konkuk University; Y. An, Konkuk University / Department of Environmental Heath Science

As a food source for terrestrial organisms, soil algae can be alternatively used for assessing soil toxicity. However, there was a limitation to collect soil algae from the soils during soil bioassay. In this study, we performed paper-disc soil method for evaluating soil algal bioassay. Growth zone, biomass, and photosynthetic activity of representative soil alga *Chlorococcum infusionum* were analyzed in the nickel-contaminated LUFA 2.2 soil. As a result, we observed the reduction of growth zone and biomass, and inhibited photosynthetic activity after 6d-exposure. The result of this study could be indirect soil quality indicator in terms of user-friendly and efficient assay for screening soil toxicity. *This subject is supported by Korea Ministry of Environment as the GAIA project (2014000560001) and by the Basic Science Research Program of the National Research Foundation of Korea (NRF) funded by the Ministry of Science, ICT and Future Planning (2014R1A2A1A11050513) and the Ministry of Education (2013R1A1A2061386).*

MO132

Aquatic Macrophyte Species Sensitivity Distribution (SSD) - Selection of Potential Testing Species

G. Gonsior,

Due to a decision from the EFSA (European Food Safety Authority) further aquatic plant species should be tested for the risk assessment of growth regulators and herbicides. Therefore a broad range of additional species were selected and tested (*Heteranthera zosterifolia, Lysimachia nummularia, Egeria densa, Vallisneria spiralis, Callitriche palustris, Ranunculus aquatilis, Hottonia palustris, Mentha aquatic, Myriophyllum sibiricum, Nymphoides peltata, Veronica beccabunga, Potamogeton natans, Utricularia vulgaris, Ceratophyllum demersum, Glyceria maxima, Cabomba caroliniana, Wolffia arrhiza, Spirodela polyrhiza, Lemna trisulca*). The studies were performed based on OECD 239: Water-sediment *Myriophyllum spicatum* Toxicity Test or on OECD 221 Lemna sp. Growth Inhibition Test. Data will be presented with the focus on the comparability to the existing guidelines.

MO133

OECD 239: Influence of pH on the Growth of Myriophyllum spicatum

G. Gonsior,

Some herbicides show a fast degradation in test medium triggered by pH. *Myriophyllum spicatum* is able to influence the pH in a significant way during testing. Therefore, it might be advisable to stabilize test items for example in a more acidic water-sediment system to provide a refined risk assessment. Studies with different pH-regimes and puffer systems were performed based on OECD 239. Data will be presented with the focus on the comparability to the existing guidelines and effects on *Myriophyllum spicatum*.

MO134

Effect of fluorine on the photosynthetic activity of freshwater and soil algae

Y. Chae, D. Kim, Konkuk University; Y. An, Konkuk University / Department of Environmental Heath Science

Fluorine can be harmful to humans and ecosystem. Uptake of excessive fluorine can cause skeletal and dental fluorosis to humans, and necrosis and interveinal chlorosis to plants. Fluorine can inhibit efficiency of photosynthesis to plants. Here, we investigated the toxicities of fluorine on the photosynthetic capacity of green algae living in aquatic and terrestrial ecosystems. *Chlamydomonas reinhardtii*, *Pseudokirchneriella subcapitat*a and *Chlorococcum infusionum* were used as test species and sodium fluoride was test material. To investigate the adverse effects of fluorine on the photosynthetic activity of algae, 9 parameters (absorption flux, trapped energy flux, electron transport flux, dissipated energy flux per reaction center, maximum quantum yield of primary photochemistry, quantum yield of electron transport, quantum yield of energy dissipation, average quantum yield of primary photochemistry and blockage of electron transfer from the reaction center to the quinone pool) were measured via Handy Plant Efficiency Analyzer. We observed that fluorine adversely affected photosynthetic function at relatively high fluorine concentrations. These results indicate that fluorine can be harmful to the primary producer of aquatic and terrestrial ecosystem and harass the food web, trophic level and, by extension, health of ecological system

Acknowledgement - This research was supported by Korea Ministry of Environment as the GAIA project (2013000530001, 2014000560001).

MO135

Effect of heavy metals on invasive knotweed (Fallopia spp.) and the combined effect of metal pollution and plant colonization on MultiDrug Resistance (MDR) phenotypes in soil bacteria

S. Michalet, Université Lyon1 / UMR Ecologie Microbienne; S. Rouifed, UMR CNRS 5023 LEHNA / UMR LEHNA; C. Backes, G. Meiffren, UMR CNRS 5557; S. Nazaret, UMR CNRS 5557 / Laboratory of Microbial Ecology Université Lyon; F. Piola, UMR CNRS 5023 LEHNA

The presence of heavy metals in the environment, which is largely due to anthropic activities, represents a stress for all living organisms, impacting ecosystem structure and function. At the microbial scale, the cellular toxicity of metals could alter microbial communities by enhancing MDR bacterial phenotypes through mechanisms of resistance co-selection [1]. Some plant species are able to grow on heavy metal polluted soil; this is the case of the invasive complex *Fallopia* which is able to accumulate metals, leading this plant to be dominant in high polluted urban environment [2]. On the other hand plants are known to be major drivers of soil microbial communities structure and functioning through root exudation [3], and *Fallopia* has been shown to exert significant effects on soil bacterial communities through its secondary metabolites content [4]. In this context we wanted to evaluate the effect of metal pollution on *Fallopia* belowground secondary metabolism, and the combined effect of metal pollution and plant colonization on soil bacterial MDR resistance phenotypes. In this aim, we undertook mesocosm experiments where rhizome fragments of *Fallopia* spp.were grown in greenhouse in soil pot artificially polluted or not with heavy metals (Pb, Zn, Cd, Cr). Our results show that (i) heavy metals delay plant growth at high concentrations but did not affect plant height after 3 months nor aerial part dry weights, only belowground part dry weights were lowered; (ii) each plant genotype could be discriminated on PCA plots at each collecting time, but the effect of metals was only detectable for both belowground plant parts (roots and rhizomes) at 1 month and not at 3; (iii) the antibiotic resistance profiles of soil bacteria were affected by plant or metals but the combined effect of plant and metals was not explained by addition effects, but rather by interaction effects which indirectly confirms the importance of metal-induced change on plant metabolism. Higher tier toxicity testing with microalgae: do light irradiation and species interaction count?

G. Cheloni, Institute FA Forel; V. Gagnaux, EPFL Swiss Federal Institute of Technology; V. Slaveykova, University of Geneva / Section of Earth and Environmental Sciences Institute Forel

Single species tests are generally performed under standardized conditions. Although very important to provide first information about the pollutant toxicity, the results of these tests lack to provide information on the potential influence of environmental factors on species sensitivity to the pollutant. In the natural environment multiple variables play a role in determining the effects of pollutants on microalgal species. Contaminants and physical-chemical factors might act as multiple stressors that simultaneously influence algal cells whereas algal species, besides having different sensitivities to the stressors, might positively or negatively interact. In this work copper toxicity to monoalgal and mixed cultures of *Chlamydomonas reinhardtii* and *Synechcystis* sp. was investigated under three different light levels, ranging from low to saturating light. The use of flow cytometry allowed the simultaneous measurement of multiple parameters (growth, chlorophyll fluorescence and oxidative stress) after 24 and 48 hours incubation in monoalgal and mixed cultures. The obtained EC50 values were used to compute Species Sensitivity Distributions (SSD) in order to verify to what extent parameters such as HC5 change in case higher tier tests that take into account high light stress and species interactions are performed. *Synechocystis* sp. resulted to be more sensitive to copper than *C. reinhardtii* under low light intensities. Surprisingly *C. reinhardtii* EC50 shifted to higher values when the alga was incubated under saturating light. Higher EC50 were also obtained when C. *reinhardtii* was co-cultures with Synechocystis sp.. On the other hand no significant changes in EC50 were observed for *Synechocystis* sp. under all tested conditions. Even if some significant differences were observed, overall the tested variables didn't cause considerable changes in EC50 values, as a consequence no significant differences were observed in the HC5 obtained from the computed SSD. In this work the difference in species sensitivity resulted to be more relevant than the changes in sensitivity that might occur for one species in presence of variables levels of light or species interaction. In the optic of using SSD for risk assessment, the choice of a group of species representative of the diversity and sensitivity that characterize the microalgal group might be more important than the realization of higher tier toxicity tests that take into account environmental factors as variable.

MO137

Impact of copper (Cu) and arsenic (As) on the biomarkers of Myriophyllum alterniflorum in an open recirculated system

M. Krayem, M. Baydoun, University of Limoges; P. HOURDIN, University of Limoges / Université de Limoges FR GEIST Groupement de Recherche Eau Sol et Environnement GRESE EA Limoges France; J. Lenain, Université de Limoges; Z. Saad, V. Kazpard, Lebanese university; V. DELUCHAT, P. LABROUSSE, University of Limoges / Université de Limoges FR GEIST Groupement de Recherche Eau Sol et Environnement GRESE EA Limoges France

For several years, heavy metals have attracted attention due to their abundance and persistence in the environment and their toxicity to human health, animals and plants. *Myriophyllum alterniflorum* DC. (Haloragaceae) is an aquatic macrophyte found in the Limousin rivers (France) notably in the Vienne River whose potential for biomonitoring of metal pollution has been well demonstrated in particular for copper, cadmium and arsenic pollutions. The objective of this study was to identify in this species sensitive biomarkers for the early detection of a river pollution taking into account the hydrodynamic conditions. Oligotrophic synthetic medium with similar composition to the river Vienne was prepared. Watermilfoils were cultured for 21 days with or without contamination by 100 µg/L copper or arsenic in aquariums system (150 L). They were placed in three hydrodynamic zones: quiet, turbulent and laminar flow zone at a rate of 3 cm/s. During this period, physiological biomarkers (respiratory and photosynthetic activities and osmotic potential), biochemical biomarkers (chlorophyll a, b and carotenoids pigments and H_2O_2 content), and morphological biomarkers were recorded. Both contaminants caused an oxidative stress characterized by the generation of hydrogen peroxide, a decrease in the pigments content, osmotic potential, photosynthetic and respiratory activities whatever the hydrodynamic conditions. In addition, a decrease in root length occurs with both contaminants and a decrease in the shoot length only appears during arsenic contamination. This decrease in root and shoot lengths was higher in turbulent than in laminar zone. Therefore, we can consider that biochemical biomarkers as H_2O_2 and pigment content, physiological biomarkers as respiration, photosynthesis and osmotic potential and morphological biomarkers especially as root length were the sensitive biomarkers for Cu and As detection in water. While only morphological biomarkers of watermilfoil were affected by the hydrodynamic conditions. Simultaneously, others biomarkers will be studied like histological biomarker such as micronuleii formation in roots. **Keywords:** *Myriophyllum alterniflorum*, copper, arsenic, biomarker, hydrodynamic conditions

MO138

Interest of using aquatic macrophyte, Myriophyllum alterniflorum, for early stage detection of pollution by copper or arsenic.

M. BAYDOUN, M. KRAYEM, P. HOURDIN, V. DELUCHAT, P. LABROUSSE, University of Limoges / Université de Limoges FR GEIST Groupement de Recherche Eau Sol et Environnement GRESE EA Limoges France

Aquatic macrophytes are important to assess the water quality, notably through the Macrophyte Biological Index in River. They can also be used to fight against pollution. For several years, GRESE laboratory studied watermilfoil to determine its potential use to evaluate environmental contaminations. Alternate watermilfoil, *Myriophyllum alterniflorum*, presents potentially useful biomarkers for the early detection of pollutants but also a significant ability to bioaccumulation. The aim of this study is to identify, in alternate watermilfoil, the most sensitive biomarkers for an early detection of surface water pollution by trace elements such as copper (metal) and arsenic (metalloid). The alternate watermilfoil is cultured *in vitro* for 21 days in a medium contaminated by copper or arsenic at concentrations of 100 and 500 μg.L^{-1}. Several physiological (osmotic potential, photosynthesis, respiration) and biochemical (Glucose6PhosphateDeHydrogenase (G6PDH), malondialdehyde (MDA)...) biomarkers are studied. Simultaneously, the physicochemical parameters of the medium are also investigated and the evolution of the concentration of the pollutant in the watermilfoil tissue is monitored. According to contaminant nature and concentration, biomarkers responses are different. Indeed copper and arsenic reduce differently the respiratory and photosynthetic activities, pigments contents and nitrate reductase activity with a decrease ranging from 10% with copper at 100 μg.L^{-1} to 60 % at 500 μg.L^{-1}; and from 15% with arsenic at 100 μg.L^{-1} to 66 % at the higher concentration (500 μg.L-1). In reverse, G6PDH activity, MDA, proline and osmotic potential, increase from 20% to 70% with the increase in copper concentration. While this increase is more important with arsenic ranging from 30% at 100 μg.L^{-1} to 85% at 500 μg.L^{-1}. Compared to copper, higher impact of arsenic on the biomarkers of *Myriophyllum alterniflorum* is observed. These differences were due to the properties of the two contaminants: one is a trace element (Cu), but becomes toxic above certain concentrations; the other (As) is a non-essential and toxic element. Once the most relevant biomarkers were identified *in vitro*, their responses would be evaluated in *in situ*-reintroduced watermilfoil on sites impacted by urban, industrial or agricultural activities. This study should allow identification of effective tools for biomonitoring of aquatic environments. **Keywords:** *Myriophyllum alterniflorum*, inorganic pollutants, biomarker, biomonitoring.

MO139

Is herbicide toxicity on marine micro-algae influenced by the natural Dissolved Organic Matter (DOM)?

N. Coquillé, IRSTEA Bordeaux / Ifremer Nantes / EPOC (LPTC); S. Stachowski, IFREMER; S. Morin, Irstea / UR EABX; E. Parlanti, University of Bordeaux / UMR EPOC LPTC; D. Menard, IFREMER / Laboratory of Ecotoxicology; J. Rouxel, L. Haugarreau, V. Dupraz, IFREMER; M. Eon, J. Vedrenne, S. Boutry, J. Rosebery, J. Ezzedine, J. Grégoire, Irstea / UR EABX; H. Budzinski, N. Tapie, P. Pardon, L. Chevance-Demars, University of Bordeaux / UMR EPOC LPTC

As primary producers, microalgae can be directly affected by herbicides. These organisms can also be impacted by other environmental elements such as the dissolved organic matter (DOM), that may also interact with pesticides. Indeed, MOD can affect pollutant transport, fate, biodegradation, bioavailability, and toxicity on organisms. Therefore, the present study aimed to investigate whether natural DOM influence the toxicity of three herbicides (irgarol (I), diuron (D) and S-metolachlor (S)), single and in mixture, on two marine microalgae, *Chaetoceros calcitrans* (*Cc*) and *Tetraselmis suecica* (*Ts*). After 6-day exposures to each herbicide (I0.05 and I0.5 μg.L^{-1}; D0.05 and D0.5 μg.L^{-1}; S0.5 and S5 μg.L^{-1}) and to mixtures (M1: I0.05+D0.05+S0.5 and M2: I0.5+D0.5+S5), the effects of herbicides were assessed on growth (doubling time T_D), photosynthetic yield (Y_{eff}), reactive oxygen species presence and intracellular relative lipid content. For each condition, two sets of triplicates were run: one with natural DOM added to the culture media, another without DOM. Without DOM, I0.5 and M2 significantly affected almost all parameters with similar trends in both species: an increase of T_D by more than twice (+125% and +129% for *Cc* and *Ts* respectively, at I0.5), a decrease of Y_{eff} (approximately 30%) and a decrease of the relative lipid content. The M2 impacts observed in *Cc* were similar to the effects induced by irgarol at 0.5 μg.L^{-1}, however a higher toxicity was shown for *Ts* (+167% for T_D), suggesting a possible synergistic effect of mixture. When DOM was added in the culture media, significant effects were also observed with I0.5 and M2 conditions for both species: while the effects of I0.5 in T_D of *Cc* were decreased (+101%), they were strongly enhanced for *Ts* (+178%), as were the effects of M2 (+298%). The presence of DOM decreased the herbicide toxicity for *Cc* whereas toxic effects were increased for *Ts*. These results may partly be due to the complexation between DOM and herbicides, leading to a lower bioavailability of herbicides. However, the difference in toxicity between the two species remains to be explained. Analysis of herbicide concentrations, dissolved organic carbon concentration and DOM, which are still ongoing, will help to improve the understanding of interactions between microalgae, herbicides and DOM. Finally, this study demonstrates the importance to consider DOM as a major factor possibly involved in toxicity modulation in the environment.

MO140

Sensitivity of duckweed species in different test designs

T. Turek, K. Brzozowska-Wojoczek, Institute of Industrial Organic Chemistry Branch Pszczyna; H. Rzodeczko, Institute of Industrial Organic Chemistry Branch Pszczyna / Dpt of Ecotoxicology; P. Fochtman, IPO Pszczyna

The sensitivity of the test organism and the test design are important issues in planning ecotoxicological studies. The aim of the study was to demonstrate that the test design affects the sensitivity of aquatic plants. In the study three species of duckweed: the swollen duckweed *Lemna gibba*,thecommon duckweed *Lemna minor*,and the giant duckweed *Spirodela polyrhiza* were exposed to a reference substance 3,5-dichlorophenol in different test designs. A static and a semi static designs, with or without sediment were used. The tests were performed according to OECD TG 221 (2006). The endpoint values were determined on the basis of the frond number and the dry weight. Generated results were statistically analysed. *Lemna minor* and *Lemna gibba* exposed in the static tests were less sensitive, regardless of whether the system was with or without sediment. However, the presence of sediment in the system affects the sensitivity. *Lemna minor* and *Spirodela polyrhiza* seemed to give a similar response, and in the semi-static test without sediment the most toxic impact of the reference substance was observed. *Lemna gibba* appeared to be the most sensitive in the semi-static test with sediment. When comparing these three species, the generated results indicate that *Spirodela polyrhiza* is the most sensitive one. Despite that the model organism used is the floating duckweed, the exposure in various test systems may have implications for ecological relevance to generated results.

MO141

Tissue damage assessment in the macrophyta Lemna gibba exposed emerging contaminants using image analysis

A. Sobrino-Figueroa, Universidad Autonoma Metropolitana Iztapalapa / Hidrobiologia Laboratorio Alejandro Villalobos; A. Dalabi-Sobrino, UCSJ

Emerging contaminants are products that are used daily, an example of these products are mouthwashes. The presence of these compounds in the wastewater is a problem that has been intensifying for 10 years, since in countries like the United States, Canada, Switzerland and France have identified their components in ppm concentrations. Because there is not information on the effect of these products on aquatic organisms, the aim of this study was to evaluate the toxicity 4 mouthwashes (Astringosol, Bexident, Colgate and Listerine) in the macrophyte *Lemna gibba*. Bioassays were performed with a duration of 6 days. Macrophytes (10 colonies) were exposed to 5 concentrations of products (25, 12.5, 6.5, 3.12 and 0.78%) in duplicate. After the exposure time, photographs were taken of each test and analyzed with the software Motic (ver. 2.3), for to evaluate the degree of chlorosis (tissue areas where chlorophyll is degraded) and necrosis (loss of living tissue) of fronds and relate to their degree of lipoperoxidacción. The product that caused the greatest degree of necrosis in the macrophytes was mouthwash Colgate (95.2%) and which had the lowest effect was Bexident (24.7%). The levels of lipid peroxidation have a direct relationship with the degree of necrosis. The analysis of the state of the fronds using the technique of image analysis, it allowed to make the evaluation of damage caused by xenobiotics more accurately, quickly and inexpensively so is a good tool for evaluating effects.

MO142

Toxicity effects of herbicide mixtures on the eelgrass Zostera noltei

N. Diepens, Wageningen University; E. Buffan-Dubau, ECOLAB UMR CNRS UPS INPT; J. Kallerhoff, ECOLAB UMR CNRS UPS INPT / Ecolab Laboratoire décologie fonctionnelle et environnement; G. Merlina, ECOLAB UMR CNRS UPS INPT; J. Silvestre, ECOLAB UMR CNRS UPS INPT / ECOLAB UMR CNRS UPS INPT; H. Budzinski, University of Bordeaux / UMR EPOC LPTC; I. Auby, IFREMER Arcachon; A. Elger, University of Toulouse / EcoLab

Seagrasses play an important role in coastal ecosystems. Worldwide seagrass declines have been observed due to multiple stressors. One of these stressors is the mixture of pesticides used in intensive agriculture in coastal areas. Effects of mixture toxicity are complex and poorly understood. The knowledge about such effects is limited as the main focus of environmental risk assessment is on single compounds. However, mixture toxicity is reality and thus more ecologically relevant. The aim was to gain understanding about short-term effects of realistic herbicide mixture exposure on the physiology of the eelgrass *Zostera noltei*. For that purpose, macrophytes collected *in situ* were exposed at different concentrations of mixtures simulating the composition of typical cocktails of contaminants in two French coastal lagoons. One experiment was conducted using a mixture of 60% 2,4-MCPA and 40% bentazone representative of the Vaccarès lagoon, Camargue (Mediterranean coast). Another used a mixture of 55% S-metolachlor, 15% atrazine, 15% diuron and 15% cybutryne (irgarol), representative of the Arcachon lagoon (Atlantic coast). Three biomarkers of stress were measured: quantum efficiency of photosystem II, photosynthetic pigment composition and enzymatic activity of glutathione reductase at different time points and total concentrations of herbicide mixtures. Data of the Camargue laboratory exposure experiment were compared with field measurements on photosynthesis and pigment contents. Data showed that environmental realistic mixtures and concentrations had sublethal effects on *Z. noltei*. Photochemical efficiency showed significant decrease at a total mixture concentration of 10 μg/L after 6h or 1 μg/L after 24 h (Arcachon mixture) and at a concentration of 10 μg/L after 24h (Camargue mixture). Effect on pigment composition was detected after 24h. Multivariate analysis of the pigment composition showed primarily a shift in the zeaxanthin:violaxanthin ratio. Field measurements did not show large differences in photochemical efficiency. Field effects were difficult to directly relate to herbicide stress as other stressors were also involved. Understanding effects of realistic chemical mixtures on sublethal endpoints of seagrasses will help to improve ERA and more efficient management strategies to prevent further declines of seagrass meadows worldwide.

MO143

Toxicity of hydrocarbons to blue green algae and higher plants to fulfil SSD requirements

C.V. Eadsforth, Shell International / Shell Health; M. Comber, Mike Comber Consulting; M. Leon Paumen, ExxonMobil Biomedical Sciences / ExxonMobil

Biomedical Sciences TES Division; K. den Haan, CONCAWE / Petroleum Products Safety; H. Hermes, IBACON GmbH; A. Seeland-Fremer, IBACON GmbH / Aquatic Ecotoxicology; V. Wydra, IBACON GmbH
Following submission of REACH dossiers on petroleum substances, CONCAWE decided to extend the ecotoxicity data base with cyanobacteria and a higher plant species, in response to an ECHA observation that test results on these species were not included in the TLM-model training set, as required by REACH Chapter R10.3.1.3. A number of single hydrocarbons (e.g. toluene, xylene, 1,2,3,4-tetrahydronaphthalene, 1-4-diethyl benzene, methylcyclohexane and 1,2-dimethylcyclohexane) covering a range of hydrophobicity were tested. Toxicity data were generated initially on two aquatic macrophytes (*Lemna gibba and Myriophyllum spicatum)* for toluene and 1,2,3,4-tetrahydronaphthalene, with the remaining four hydrocarbons tested only on *Lemna*. Toxicity data were generated on the blue green algae (*Anabaena flos-aquae*) for all the hydrocarbons. A range of test concentrations of each hydrocarbon were generated by sequential dilution of a saturated solution in test media. Care was taken to minimise loss of test compounds during test media preparation and transfer of test solutions. Toxicity of these hydrocarbons ranged from ~ 1 – 30 mg/L (72h E_rC_{50}) for blue green algae and from ~2- 70 mg/L (7 day E_rC_{50}) for *Lemna* with expected lower toxicity values with an increase in hydrophobicity**.** The two sets of data were well correlated (r^2 = 0.954) Blue green algae were consistently less sensitive (2-3 x) than green algae to these hydrocarbons, and consistently more sensitive (approx. 2-3 x) than *Lemna*.

MO144
Toxicity screening of pesticides towards two marine phytoplankton species
V. Dupraz, IFREMER, RBE-BE-EX; S. Stachowski, IFREMER; D. Menard, IFREMER / Laboratory of Ecotoxicology; F. Akcha, IFREMER; M. Devier, H. Budzinski, University of Bordeaux / UMR EPOC LPTC
The PHYTOCOTE project, funded by LabEX COTE, concerns the use of pesticides in Aquitaine vineyards (France), their transfer and impacts on ecosystems. As primary producers, microalgae are at the bottom of the aquatic food web and are of great concern for aquatic ecosystems. In the frame of the "impacts" task of the project, this work aims to develop a screening method to assess and compare the toxicity of several active substances for two marine microalgae commonly used in aquaculture: *T-isochrysis galbana* (chrysophyte)and *Skeletonema costatum* (diatom). The tested pesticides are the herbicides diuron (phenylurea) and S-metolachlor (chloroacetanilide) and the insecticides fipronil (phenylpyrazole) and imidacloprid (neonecotinoid). These screening results will allow us to select substances and species in order to evaluate, at the laboratory scale, the trophic transfer of pesticides from microalgae to a primary consumer (oyster), as well as the induced effects. The screening test consists in 5-day exposures of microalgae cultures to contaminants using sterile 24-well microplates in controlled conditions. Microplate wells are filled with 1.5 mL of sterile culture media and inoculated with cultures (initial concentration of 2×10^4 cell.mL^{-1}). The two microalgae strains are exposed to 5 concentrations of each substance, (3 replicates per concentration and 6 replicates for the control). Growth inhibition, the endpoint selected, is estimated daily by measuring the chlorophyll fluorescence at 685 nm using a microplate reader. At the end of exposure, each well is sampled to determine i) the cell density by flow cytometry and ii) the effective exposure concentration by chemical analysis. EC_{50} are then calculated for each substance and species. These tests are currently ongoing. Preliminary results indicate a variable stability of the substances in the microplate wells within the 5-day exposure, due to plastic adsorption and/or degradation. In our experimental conditions, a linear relationship was obtained between the chlorophyll fluorescence at 685 nm and the cell density measured by flow cytometry. The two microalgae species do not react similarly when exposed to the pesticides. Herbicides are more toxic than insecticides. Finally, this study will provide toxicity data about several substances on the first trophic levels of aquatic ecosystems: primary producers in one hand, and primary consumers exposed by their diet in the other hand.

MO145
Determination of Plant uptake factor (PUF) values with two different crops and two different pH levels in uptake solution under greenhouse conditions
V. Gourlay, A. Leonhard, G. Fent, R. Kubiak, RLP AgroScience IfA
Plant uptake of pesticides is an important process limiting their availability for leaching, run-off and volatilisation. Chemical hydrophobicity ($\log K_{ow}$) and acid dissociation (pK_a, for ionisable compounds) are the most important properties determining the ratio between the concentration of compound in the plant-root system to that in the pore water adjacent to the roots. The plant uptake factor is used as input parameter in environmental fate mathematical models, such as leaching models (e.g. FOCUS, PEARL). Based on the experimental guideline EUregPUF (**2013**, draft), the standard test system was improved and a ring-test was organized (Lamshoeft et al, **2015**). The plant uptake factor was measured in soil-free hydroponic test systems with intact wheat plants where the root system was incubated in pH 6.5 buffered aerated artificial pore water solution containing a given concentration of the compound. The solutions were continuously aerated and protected from light to avoid algae. By monitoring the cumulative volume uptake and the concentration of the test item in the solution at different time intervals, plant uptake factor values could be calculated. Prior to application, the plants were incubated in non-treated test systems and let to recover. The same test system as for the ring-test was used in this study, with incubation durations of about eight days under greenhouse conditions. As for the ring-test, 1,2,4-triazole was used as test compound. In this study, oilseed rape and maize plants were investigated, together with buffered solutions to pH 6.0-6.5 and pH 7.3-7.8. The plant uptake factor was determined on several sampling dates (e.g. 2, 5 and 8 days after treatment), as well as in the test plants at the end of cultivation, using the equation given by Sweeney (**2014**, submitted).

MO146
Experiments and inverse modeling to plant uptake and degradation of eight emerging organic contaminants
C. Hurtado, IDAEA-CSIC; S. Trapp, Technical University of Denmark / DTU Environment; J. Bayona, IDAEA-CSIC / Environmental Chemistry
A myriad of emerging organic contaminants (EOCs) have been detected in reclaimed water. These contaminants are usually not regulated in effluent water. Among them there are many pharmaceutical and personal care products (PPCPs), biocides, and other chemicals used by households and industry. In arid and semiarid countries, reclaimed water is frequently used for irrigation of agricultural crops. Several studies have reported that a number of EOCs are taken up well by plants. Hence, human exposure to those chemicals can be associated with the use of reclaimed water for crops. Several empirical and process-based models have been developed for the prediction of concentrations of EOCs in plants. Accordingly, adsorption to soil, lipophilicity and the speciation of the chemical (neutral or ionized) are the governing properties for the uptake and translocation to edible parts. A mesocosm study in a greenhouse facility was carried out to experimentally determine the uptake of eight EOCs (bisphenol A, caffeine, carbamazepine, ibuprofen, propranolol, sulfamethazine, tonalide, triclosan). Batavia lettuce (*Lactuca sativa* cv. Arena) was grown in a perlite:sand mixture with five concentrations of the eight compounds (0, 12, 29, 58 and 117 μg kg^{-1}). 28 days after starting to water the plants with contaminants, the concentrations in substrate, roots and leaves were determined using gas chromatography (GC) and ultra-performance liquid chromatography (UPLC) coupled to tandem mass spectrometry (MS/MS). Uptake into plants was highest for carbamazepine. Most compounds were rapidly degraded, as seen from the difference in initial and final concentrations within the substrate. Inverse modeling with the standard plant uptake model was used to estimate degradation. Measured dissipation was contrasted with physico-chemical loss (volatilization, translocation, dilution) and the difference was contributed to biodegradation in plant. This indirect method cannot prove degradation but can help to quantify loss processes. Two degradation kinetics were fitted to experimental data, namely first order and Michaelis-Menten. Highest degradation rates in plants were calculated for caffeine (leaves), propranolol (leaves) and ibuprofen (roots and leaves). Of course this method bears some uncertainties but is a first step to consider degradation inside plants, which is widely unknown but essential for predictions of human exposure to EOCs.

MO147
Sorptive capacity of rhododendron leaves for organic pollutants measured using passive dosing: Lipid characterization and passive dosing experiments
D.J. Bolinius, Stockholm University / Department of Environmental Science and Analytical Chemistry ACES; M. MacLeod, ITM - Stockhom University / Department of Environmental Science and Analytical Chemistry ACES; A.H. Kierkegaard, F. Iaderasta, J. Holmbäck, Stockholm University / Department of Environmental Science and Analytical Chemistry ACES; A. Jahnke, Helmholtz Centre for Environmental Research UFZ / Cell Toxicology
Leaves play an important role in the cycling of semi-volatile organic pollutants as a result of their large surface area and lipid rich cuticle. Semi-volatile pollutants that are scavenged from the atmosphere by leaves can be transferred to the soil through the shedding of waxes and litter [1], where they will either be trapped or re-released to the atmosphere upon decomposition of the plant material. Most multimedia chemical fate models use either an octanol-equivalent model for leaves (e.g., BETR) [2] or reported values from the literature for specific species under the assumption that all plant species have the same sorptive capacity (e.g., CoZMo-POP) [3]. It has been shown, however, that the sorptive capacities of different plant species can vary considerably [4]. In this study we modified an existing passive dosing system to measure the sorptive capacities of the extractable organic matter (EOM) of rhododendron leaves, and characterized the lipids present in the EOM by ^{1}H-NMR spectroscopy in combination with LC-MS and LC-ELSD. While the previous set-up succeeded in reaching equilibrium for cyclic volatile methylsiloxanes within 9 days, the kinetics of equilibration were considerably slower for chlorobenzenes and low chlorinated PCBs. By introducing a fan into the lid of the passive dosing system we were able to enhance the kinetics so that we reach equilibrium as well for dichlorobiphenyls and hexa-chlorobenzene within the same amount of time. This system is used to compare the sorptive capacities of a wide variety of leaves including Norway spruce, douglas fir, red oak, common reed, European beech, rhododendron and the European alder and will provide additional data about variability between plant species that can be compared with existing literature data and that will support

multimedia modeling. **References:** 1. Horstmann, M. & Mclachlan, M. S. Atmospheric deposition of semivolatile organic compounds to two forest canopies. *Atmos. Physiological responses of date palm (Phoenix dactylifera L) exposed to air and soil pollution near the industrial complex in Sfax, Tunisia

M. Zouari, C. Ben Ahmed, N. Elloumi , Faculty of Sciences of Sfax / Laboratory of Plant Biodiversity and Dynamics of Ecosystems in Arid Area; D. Delmail, University of Limoges / Laboratory of Botany and Cryptogamy; B. Ben Rouina, Olive Tree Institute of Sfax / Laboratory of Improvement of Olive Productivity and Fruit Trees; F. Ben Abdallah, Faculty of Sciences of Sfax / Laboratory of Plant Biodiversity and Dynamics of Ecosystems in Arid Area; M. Baydoun, University of Limoges; P. Labrousse, Université de Limoges

This study aims to evaluate the impact of complex air and soil pollutions on date palm plants (*Phoenix dactylifera*), one of the most important commercially valuable crops in Tunisia. These field experiments were performed in the vicinity of the industrial complex in the south of Tunisia (Sfax) for the polluted samples and in unpolluted areas for control date palm plants. Several biomarkers were studied belonging mainly to the antioxidant system like enzymes or antioxidant compounds. Mains results indicate that air and sol pollution induced an oxidative stress as demonstrated by an increase in the rate of hydrogen peroxide (H_2O_2) production, electrolyte leakage and lipid peroxidation in all plant parts. This stress affects chlorophyll and carotenoid contents of leaves. Additionally, the activities of enzymes involved in reactive oxygen species (ROS) detoxification were affected. Air and soil pollution induce an increase in the activities of ascorbate peroxidase (APX), glutathione peroxidase (GPX), superoxide dismutase (SOD) and catalase (CAT). Moreover, in polluted date palm plants the contents of antioxidant molecules like polyphenols and proline increase strongly, this is consistent with the role of these potent antioxidants in scavenging ROS. The present study evidenced the deleterious effects of industrial activity on antioxidative defense system of *Phoenix dactylifera*, an important crop species spreading in arid region of Tunisia.

MO149

Variation of nectar sugar content in different flowering plants

P. Mack, J. Wong, Eurofins Agroscience Services Ecotox GmbH; S. Knaebe, Eurofins Agroscience Services Ecotox GmbH / Ecotoxicology Field

Pollinators need nectar for survival and provision of the next generation. They choose nectar with higher sugar content and thus higher energy ratio for consumption. There is a lower limit to sugar content where it is not viable for pollinators to visit the respective nectar source again (US-EPA 2012). The EFSA guidance document "on the risk assessment of plant protection products on bees" (2013), provides default values of nectar sugar content for the risk assessment. These worst-case values are the lowest sugar content which may be foraged by the pollinators. The rationale behind these default values is that higher sugar content will result in reduced nectar consumption and therefore a lower exposure to pesticides present in the nectar. The values are based on literature research. The default values given for the risk assessment in crop are 15 % nectar sugar content for honey bees and bumble bees and 10 % nectar sugar content for solitary bees. For weeds and the field margin the default value is 30 %. For the low default value in crop there is the option to refine the risk assessment with experimental data. We present nectar sugar content values from different plant species. Nectar samples were acquired by manual sampling from flowers directly or were collected from honey stomachs of forager bees. We compare the variation in nectar sugar content between the different sampling methods and discuss the distinct sampling procedures. **United States Environmental Protection Agency (2012) White Paper in Support of the Proposed Risk Assessment Process for Bees; submitted to the FIFRA Scientific Advisory Panel for Review and Comment. European Food Safety Authority (2013) Guidance on the risk assessment of plant protection products on bees (Apis mellifera, Bombus spp. and solitary bees). EFSA Journal (2013) 11(7):3295, 266 pp.**

Inherent variability in non-target terrestrial plant (NTTP) testing is an ongoing issue with respect to the use and interpretation of these data for risk assessment. Statistical differences from control groups are often a product of natural variability, with no apparent biological consequence associated with these differences. Such statistical artifacts can lead to a requirement to conduct multiple concentration/rate studies versus single concentration/rate limit tests, the appearance of non-monotonic dose-response curves which are simply natural variability in the data, or an assumption of risk when there are statistical differences from controls of even a few percent. Standardized NTTP testing protocols were initially designed to calculate ER25 (used in the U.S.) or ER50 (used in Europe) values for various effect measures, including sub-lethal measurements of growth. Recent recommendations for risk assessments to consider 5% effect values (ER05s) in the place of non-definitive NOERs (such as for endangered species assessments) should be approached with caution. Extrapolating to an ER05 can result in values which may simply represent natural biological variability and lead to risk assessment conclusions that may overestimate risk. To address these concerns, we evaluated historical control data from standard seedling emergence and vegetative vigor studies (more than 30 studies of each type). The objectives of this statistical study were to determine the variability of control results across studies for each plant species, examine possible causes for the variation in control results across studies, and, given the inherent variability of controls within each study, determine the percent effect that can be estimated or minimum percent effect that can be detected statistically. Findings indicate that when the control variability is high, only very large effects are statistically significant. The results from this analysis indicate that with current test design and implementation, it will often be impossible to estimate an ER05 and will rarely be possible to estimate an ER10. Furthermore, there is no single ECx that fits all situations because the inherent variability depends on the test type, species, and growth response parameter. This analysis focused on statistical significance only. Biological significance is a separate and important consideration.

MO151

Establishing field studies as a potential higher tier option to refine risk assessment for non-target terrestrial plants

R.J. Isemer-Kellner; C. Mihan, A. Solga, D. Jans, Bayer CropScience AG; P. Sowig, Bayer CropScience AG / Ecotoxicology; M. Dollinger, Bayer CropScience AG / Environmental Safety Ecotoxicology; T. Hall, Bayer CropScience / Environmental Toxicology and Risk Assessment

During the regulatory approval process for pesticides, potential side-effects to non-target terrestrial plants (NTTP) need to be assessed. Routine testing with NTTPs is done in highly standardized greenhouse studies. However, if the obtained results are not sufficient to demonstrate acceptable risk, higher tier testing may be needed. Field studies are frequently mentioned as higher tier options but so far no agreed method has been established. Here we present results of a pilot field study done in order to establish a higher tier method for refining risk assessment for NTTPs. Complexity of NTTP field studies is pointed out and discussed. A homogeneous distribution of plant species in the study field is an important prerequisite for data evaluation in the risk assessment paradigm. Hence, commercially available seed mixtures were evaluated as a potential source for establishing higher tier study sites. In a preceding field study conducted in 2014, it was found that both seed mixture and growth area greatly influence distribution of species. Accordingly, in the present field study conducted in 2015 five different seed mixtures were compared in two distinct locations in Germany with regard to their potential for establishment of a homogeneous species coverage. The two locations differed with regard to soil type, irrigation and amount of seeds sown. To reduce emergence of species from the soil seed bank, soil preparation measures were taken at both sites (herbicide application or ploughing). Vegetation cover was assessed according to an extended Braun-Blanquet scale in four replicates per seed mixture on a monthly basis during the growth season (July to October). Two of the five tested seed mixtures showed acceptable results during the first months of assessment. As the study progressed, ecological processes such as competition and succession became important and will need to be considered in future study design. Emergence of plant species from the soil seed bank has to be reduced in order to establish a homogeneous coverage of plant species. About 20 species emerged from the seed bank, regardless of pre-treatments of the fields which resulted in lack of homogeneity in the study fields. Overall, the field study demonstrated that seed mixtures may represent a viable higher tier option, but there still exist some challenges which we will further examine in order to establish a suitable method for field studies for NTTPs.

MO153

A suggested minimum data list for documenting experimental plant uptake studies

S. Trapp, Technical University of Denmark / DTU Environment; W.J. Doucette, Utah State University / Utah Water Research Laboratory; P. Fantke, Technical University of Denmark / Quantitative Sustainability Assessment Division; T. Eggen, Norwegian Institute for Agricultural and Environmental Research / Bioforsk

Quantifying the plant uptake of organic chemicals is critical for assessing human and ecological risks, evaluating plants as biomonitors, predicting phytoremediation effectiveness, and for the continued development and improvement of plant uptake models. Experimental data are commonly expressed as ratios of chemical concentrations in the plant compartment of interest (e.g. shoots, roots, xylem sap) to that in the exposure medium (soil, soil pore water, hydroponic solution). These ratios are generally referred to as bioconcentration factors (BCFs) but are likely not at equilibrium. Experimental methods used to measure plant BCFs have not been standardized and vary widely. This makes inter-study data comparisons tenuous. One of the main difficulties in comparing the results of different studies is the lack of information presented on key parameters needed to compare and reproduce the results, and to assess the quality of the study. This includes information describing the experimental design (number of replicates, appropriate controls), plant growth conditions (light intensity, humidity), chemical exposure (duration, concentration), and the quality control information associated with the methods used for plant and exposure concentration analysis. Large impact is also expected from the plant parameters, such as harvest weight, dry matter content, transpiration, water use efficiency, and growth rate. It is rare that these physiological parameters are assessed. Based on a survey of the literature, simulations with physiology-based plant uptake models [1] and the direct experience of over 20 plant uptake experimentalists, we developed a suggested minimum list of data reporting requirements for experimental plant uptake studies. Moreover, we give advice on how such parameters can be obtained with relatively low efforts. The goal is to understand the observed large variations of results seen from different uptake studies, and ultimately the recommendation of a standard uptake test. **References** [1] Trapp, S. 2015. Calibration of a plant uptake model with plant- and site-specific data for uptake of chlorinated organic compounds into radish. Environ. Sci. MO154

Assessing the applicability of a proposed protocol for determining a plant uptake factor (PUF): preliminary results

Y. Sandstrom, W.J. Doucette, Utah State University / Utah Water Research Laboratory

Models for estimating the leaching of plant projection products to groundwater incorporate plant uptake as a mitigating process. Transpiration stream concentrations (TSCF) have been the key parameter used in estimating plant uptake. However, there are no standard methods for determining TSCF and considerable variation for a single chemical is often observed in the literature. A new European Crop Protection Association (ECPA) protocol, designed to determine chemical specific plant uptake factors (PUFs) from simple laboratory studies, has been proposed to replace TSCF values. The protocol is designed to calculate chemical specific PUFs from the changes in chemical mass and hydroponic solution volume measured over an eight-day period. Theoretically, PUF values range from 0 (no uptake) to 1 (complete uptake). The objective of this study was to evaluate the feasibility the proposed protocol for determining PUFs using 14C-labeled 1,2,4-triazole (log Kow = -0.58), caffeine (log Kow = -0.07) and diethylphthalate (log Kow = 2.4) and Tybalt wheat as the test plant species. Replicate plant uptake studies were conducted for each chemical. Wheat seeds were germinated in perlite then transferred to aerated hydroponic containers prior to chemical exposure. After adding the test chemicals to the hydroponic systems, measurements of chemical concentration and solution volume made over an 8-day period were used to determine PUFs. The final recoveries and the distribution of 14C were also determined by direct measurement. PUF values for 1,2,4-triazole, caffeine, and diethylphthalate were 0.21 ± 0.04, 1.07 ± 0.23, and 2.61 ± 0.83 respectively. The greater the chemical mass left in solution, the smaller the PUF. However, the PUFs were found to be inversely related to the 14C recoveries that were 95% (1,2,4-triazole), 85% (caffeine) and 52% (diethylphthalate). Volatilization from the hydroponic solution, confirmed in subsequent experiments, was the major loss mechanism for diethylphthalate resulting PUFs much higher than the theoretical maximum. It was also observed in preliminary experiments that high evaporation or transpiration rates make it difficult to determine realistic PUFs. Overall, the proposed PUF protocol is simple to conduct and relatively reproducible. However, additional studies on the impacts of evapotranspiration and chemical volatility are needed before the potential limitations of the protocol can be understood and defined.

MO155

Effect of plant species on the determination of the plant uptake factor (PUF) for use in regulatory fate modelling

M. Reitz, German Crop Protection Association, IVA; M. Lamshoeft, Bayer CropScience AG / RD; S. McCall, BASF SE; H. Resseler, Syngenta AG; S. Schubert, Dow Agro Sciences LLC; C. Schriever, BASF SE, Agrarzentrum Limburgerhof; R. Sur, Bayer CropScience AG / Environmental Safety; S. Webb, Syngenta AG; B. Zillgens, Dupont GmbH

Stakeholders from academia and regulatory authorities have proposed to develop a new study design to determine the plant uptake factor (PUF) for regulatory fate modelling [1]. The German Crop Protection Association (IVA) as well as the European Crop Protection Association (ECPA) together with contract research organizations developed and tested a new study protocol in a round robin test with [^{14}C]-1,2,4-Triazole and wheat plants at pH 6.5. Ten laboratories participated and the results confirmed that a promising new method in a hydroponic system was developed. The updated test protocol was made available at the Piacenza Symposium [2]. For a further implementation of the new procedure with different plants and various pH values, more experiments to determine PUF values of active substances and their metabolites were conducted. Here the analysis of a broad spectrum of studies is presented that were carried out by applying the new study protocol with e.g. potato, tomato, winter oil seed rape and wheat plants. The evaluation of the obtained results focused on the applicability and reliability of the protocol to establish the new method for the use in regulatory fate modelling with various plants.The findings demonstrate that with the new method a robust and reliable test can be performed to determine the PUF with a variety of different crops and agricultural relevant pH values between 5.5 and 7.5. MO156

The plant uptake factor - a regulatory perspective

K. Kuppe, German Environment Agency / Plant Protection Product; I. Bonath, Federal Environment Agency / Section IV Pesticides Fate and Behaviour Groundwater Risk Assessment; R. Herr, A. Nehls, C. Pickl, German Environment Agency

In the pesticides risk assessment, regulatory decisions are often based on results of environmental modeling. The input parameters utilized in the calculation of predicted environmental concentrations need to be reliable in terms of precision and accuracy. To meet these requirements, most input values (degradation rate, adsorption to soil particles) are usually derived from experimental studies performed according to accepted guidelines (e.g. OECD) with well established methods developed and validated by scientific experts. The plant uptake factor (PUF) is a parameter describing the ability of plants to take up substances from the soil pore water via their root systems. This specific amount of substance is not susceptible to leaching processes into groundwater. Consequently, the PUF can be a crucial modeling parameter with a high impact on regulatory decision making. This potential of the PUF for refinements of lower tier groundwater assessments has also been recognized by the pesticides industry. Over the last years, considerable effort has been expended by the industry in developing a standard study design for the experimental determination of the PUF. A preliminary study protocol was evaluated in a ring test in ten laboratories in order to obtain information on the robustness, reliability and practicability of the proposed method. In our contribution we will present an analysis and interpretation of the ring test results from a regulators point of view. A profound examination of the uncertainties associated with the PUF will consider variables influencing the PUF as well as experimental quality criteria and the implementation of the PUF in the modeling tools. Finally, we will raise the question what should be defined as “taken up” by plants and provide options for the usage of experimental PUF values derived by a none-OECD test guideline in the groundwater risk assessment for pesticides on a European scale.

Metals in the Environment: Fate, Speciation and Bioavailability in Water, Soil and Sediment (P)

MO157

The role of organic ligand source and type in governing zinc and copper speciation in the Tamar Estuary, UK

H.B. Pearson, Plymouth University / SoGEES; S. Comber, Plymouth University / Environmental Science; C.B. Braungardt, P. Worsfold, Plymouth University

Zinc (Zn) and copper (Cu) are essential elements for the healthy development of all organisms, but uptake in excess can be harmful. Metal bioavailability is governed by chemical speciation, with the free metal ion often being the most readily biologically available and therefore most toxic. Zinc and Cu are now classified as specific pollutants by the UK Environment Agency, and changes to Environmental Quality Standards (EQS) in 2013 under the Water Framework Directive have resulted in revised standards for saline waters being significantly reduced. For Cu, the new EQS of 59.2 nM dissolved (previously 78.7 nM dissolved) now takes into account bioavailability based on dissolved organic carbon (DOC) concentrations, whereas dissolved Zn is now restricted to 612 nM (previously 121 nM) including an ambient background concentration of 17 nM. This change has driven further research to investigate links between metal speciation and potential biological effects. Water samples from the Tamar Estuary (UK) have been collected seasonally over a full range of salinities (~0.1 – 35) over one calendar year. Samples were taken from locations thought to be influenced by different ligand sources (e.g. sediment derived humic and fulvic acids, sewage

effluent, algal blooms). Filtration to 0.4 μm and 0.2 μm was undertaken, and sample DOC, nutrient, and chlorophyll-a concentrations determined. Sample DOC was characterised via excitation-emission fluorescence. The total dissolved and (operationally defined) labile Zn and Cu fraction, complexation capacity (CC), complex conditional stability constants (log K) and free metal ion concentrations have been measured using adsorptive cathodic stripping voltammetry. Size fractionation reveals metal speciation in the freshwater and low salinity regions is controlled via complexation by larger colloids. Total DOC concentrations are not correlated with increased metal complexation, indicating that this parameter may not necessarily be the best indicator of potential bioavailability.
Excitatio-emission data suggests that autotrophic productivity could play an important role in governing [Zn^{2+}] in the high salinity zone.

Leermakers, Wageningen UR / Laboratory of Physical Chemistry and Colloid Science; J.F. Duval, CNRS / Laboratoire interdisciplinaire des environnements continentaux LIEC CNRS UMR
Chemodynamics studies in environmental systems are intrinsically difficult due to the heterogeneous nature of the natural matrix especially the types of colloidal and particulate ligands present in solution, their sizes and respective structural organization. In the last decade significant progresses have been made in the understanding of the chemodynamics of colloidal dispersions, namely the influence of size and charge effects, conversely our comprehension of the impact of structural effects is still rather incipient. We investigated structural effects on the chemodynamics of metal ions using two well characterized Core-shell particles made of a glassy (PMMA) core decorated by a modified PNIPAM anionic corona, synthesized using either acrylic acid (AA) or methacrylic acid (MA). Their differentiated reactivity leads to the generation of p(MA-N) and p(N-AA) particles with carboxylate charges located, preferentially in the vicinity of the core and at the shell periphery, respectively. The structural characteristics of these particles were addressed over a broad range of pH values (4 to 7.5), $NaNO_3$ concentrations (3 to200 mM) and temperatures (15 to45°C) by DLS and SANS. DLS shows that the swelling of the ~10 to 90 nm thick-particle shells with decreasing temperature, ionic strength or increasing pH is most pronounced for p(N-AA). Potentiometric titration and electrokinetics reflect the easier dissociation of carboxyl groups in p(N-AA) shell. The DLS response of both particles is attributed to the multiresponsive nature of a peripheral, diluted shell while SANS probes only the presence of a quasi-solvent free dense polymer layer condensed on the core surface. Thickness of that layer increases from ~6 to 9.5 nm with increasing temperature from 15 to45°C (15 mM and pH=5) due to the corresponding collapse of the outer diluted shell layer. Overall, the results evidence the microphase segregated shell structure of p(MA-N) and p(N-AA). The binding of Cd^{2+} ions to in p(N-AA) particles was investigated by SSCP and showed an increase in heterogeneity with temperature at pH 7.5 confirming an influence of structural changes upon the chemodynamics. This work illustrates the need of further studies in environmental colloidal and particulate systems to fully understand the effect of structural organization on chemodynamics and demonstrates the utility of characterization techniques, like SANS, to enlighten the link between structure and reactivity in these matrices.

MO159
AGNES at vibrated gold microwire electrode for the quantification of free copper at low concentration levels
R.F. Domingos, Institut de Physique du Globe de Paris / Équipe de Géochimie des Eaux; S. Carreira, Instituto Superior Técnico / Centro de Química Estrutural; J. Galceran, University of Lleida and Agrotecnio / Department of Chemistry; P. Salaün, University of Liverpool / School of Environmental Sciences; J.P. Pinheiro, Universite de Lorraine / LIECENSG UMR CNRS
The critical importance ascribed to the free ion in models, such as the free-ion activity model and the biotic ligand model, led to an increasing interest in quantifying this specie in natural media. However, there is only a limited number of techniques able to quantify the free ion concentration with the required selectivity and detection limit. **AGNES** (absence of gradients and Nernstian equilibrium stripping) technique, which was specifically designed and developed to quantify free metal ion concentrations in aquatic systems, seems an ideal technique overcoming most of the limitations of known methods such as potentiometry with ion selective electrode or Donnan membrane technique. Typically, AGNES has been implemented with mercury electrodes and most recently with bismuth electrodes. *Whereas the former gives rise to concerns regarding the toxicity of mercury, the* ***copper speciation*** *is impossible with the latter due to the similarity of their reduction potentials*. Contrarily, **gold electrodes** are well suited for Cu speciation, without the need for oxygen removal, since the metal reduction wave is at more positive potentials than the O_2 wave, avoiding changes in metal speciation. For the first time the application of AGNES at a gold electrode for the quantification of free Cu concentrations is presented. It was found that: i) the amount of deposited Cu follows a Nernstian relationship with the applied deposition potential, and ii) the stripping signal is linearly related with the free metal ion concentration. The performance of AGNES at the vibrating gold microwire electrode (VGME) was successfully assessed for two labile systems: Cu-malonic acid and Cu-iminodiacetic acid at ionic strength 0.01 M and a range of pH values from 4.0 to 6.0. This novel work implementing AGNES methodology at the VGME is of extreme importance showing that there is a highly promising alternative for Cu speciation at the low concentration levels existing in natural waters, with specific advantages coming from: i) the non-toxicity of the working electrode, and ii) the ability to perform measurements without O_2 removal. Furthermore, it highlights the potential of gold electrodes, and other solids electrodes (e.g., Ag, Sb), for the quantification of other free metal ions (e.g., Hg, Sb, As) at low concentration levels. As such, we expect that this new analytical implementation of AGNES will ultimately become an important tool for applications in environmental and toxicological studies.

MO160
Determination of free concentrations of metals with vibrating gold electrodes
D. Correa, R.F. Domingos, Institut de Physique du Globe de Paris / Équipe de Géochimie des Eaux; E. Companys, Universitat de Lleida and AGROTECNIO / Dep Quimica; J. Galceran, Universitat de Lleida / Dep Quimica; P. Salaün, University of Liverpool / School of Environmental Sciences; J.P. Pinheiro, Universite de Lorraine / LIECENSG UMR CNRS
Speciation is key to understanding availability of metals to biota. Hegemonic paradigms such as the Free Ion Activity Model (FIAM) or the Biotic Ligand Model (BLM) highlight the relevant role of free concentrations of the studied substances in the medium for their toxic or nutritional capabilities. So, there is an urgent need for developing analytical techniques able to measure free metal concentrations in all kind of environmentally relevant matrices with sufficiently low limits of detection. The electroanalytical technique AGNES (Absence of Gradients and Nernstian Equilibrium Stripping), with the Hanging Mercury Drop Electrode (HMDE), has proved efficient in measuring free concentrations of elements such as Zn, Cd and Pb in a variety of matrices: seawater, freshwaters[1], humic acid dispersions, soil extracts[2], dispersions of ZnO nanoparticles[3] or CdSe quantum dots[4], etc. However, the use of a mercury electrode implies some drawbacks such as its toxicity. So, there is an active work for the implementation of AGNES with solid electrodes. A first realization has been the determination of free Pb with a bismuth electrode[5]. On the other hand, the Vibrating Gold Microwire Electrodes (VGME) has recently tackled many systems[6]. The aim of this poster is to show recent advances in the application of AGNES with VGME to the determination of free Cu concentrations. Special attention will be paid to unravelling the physicochemical principles (such as underpotential deposition of Cu as a monolayer on the gold electrode or the presentation of mathematical expressions to relate the preconcentration factor with the applied potential), as well as to consider practical issues for its implementation in environmental matrices such as limit of detection, interferences, time of analysis, impact of solution composition, range of linearity, working potentials, and ease of operation.

MO161
PEST-ORCHESTRA: A tool for optimizing NICA-Donnan model parameters for humic substances reactivity
N. Janot, LIEC - Université de Lorraine - CNRS / Laboratoire interdisciplinaire des environnements continentaux LIEC CNRS UMR; J.S. Pinheiro, Université de Lorraine UL / Laboratoire interdisciplinaire des environnements continentaux LIEC CNRS UMR; W.G. Botero, Federal University of Alagoas; J.E. Groenenberg, Alterra Wageningen University and Research Centre / sustainable soil management
Humic substances are a complex mixture of macromolecules that have a high affinity for metal ions and can affect their mobility and bioavailability in the environment. Due to the high heterogeneity of humic substances, their reactivity is difficult to determine, and several models exist to describe their acid-base properties and their complexation to metal ions. Among the various speciation model platforms, the software ORCHESTRA has the advantages to be independent of the operating system and free. Furthermore, it is to be very flexible, since model its model definitions are in text format and thereby accessible and can be modified by users for extensions and modifications. However, until now, no method is available to optimize model parameters using ORCHESTRA. Here we describe the coupling of the PEST parameter optimization software with the ORCHESTRA speciation software, and validate this method as a way to describe humic substances reactivity within the framework of the NICA-Donnan model, by comparing our results with literature

data. The optimization procedure has been applied to obtain optimum NICA-Donnan parameters for the binding of protons and metal ions to Laurentian fulvic acid (LFA). An unconstrained fit gave us proton-binding parameters in good agreement with the results obtained by Milne et al. (2001) on the same dataset using the FIT software. This allow us to validate our approach. Furthermore, this method is applied to optimization of Pb-binding parameters for the same LFA. PEST-ORCHESTRA optimization gives results that are of the same order of magnitude than the ones obtained by Milne et al. (2003) if input parameters are identical (generic fulvic acid proton-binding parameters). However, the optimization procedure yields significantly different values when LFA-specific proton-binding parameters are used as input: $\log_{Pb,1}$ goes from -0.98 to -0.47 and $\log_{Pb,2}$ from 6.55 to -0.43, even if the calculated amounts of LFA-bound Pb are comparable in both cases. This procedure is also applied to derive parameters for Cd- and Zn binding to LFA, which were lacking till date.

MO162

Modelling and determining the varying dissolution rates of sacrificial zinc anodes on pleasure craft on the Hamble estuary, UK and its environmental implications

A. Rees, A. Gallagher, Southampton Solent University; S. Comber, Plymouth University / Environmental Science

This study investigates the physico-chemical parameters within an estuary which affect the dissolution rate of zinc sacrificial anodes on pleasure craft and the impact this has on the aquatic environment. The Hamble estuary is densely populated with around 3000 pleasure craft. Anecdotal evidence suggests zinc anodes decay faster within this estuary compared with other estuaries within the Solent. Zinc anodes are designed and used to protect vessels, fittings on vessels and marine structures from corrosion, but their use can raise zinc concentrations within estuaries, especially around marinas, as they dissolve. Estuaries can therefore sometimes exceed the zinc EQS (Environmental quality standards) limits for the UK of 7.9μg/l causing concern regarding potential impacts on marine life. A survey of boat owners has determined the type of anodes used and possible reasons for a varied dissolution rates within the Hamble. This enables 'hot spots' of anode premature wear to be identified and compared with physical parameters from these areas, which helps determine factors contributing to anode dissolution. Some of the physical parameters suggested include stray electrical currents, salinity variation and the number of boats present. Along with the MAMPEC model and water quality data collected from the Hamble the zinc load from anodes can be determined for individual marinas and the estuary as a whole. Determining these factors and the other main sources of zinc to the Hamble estuary allows the rates of anode decay and the main sources to be spatially mapped and modelled. This will contribute to management plans being re-evaluated and help estuaries such as the Hamble achieve EQS levels.

MO163

ON THE USE OF BULK METAL DEPLETION KINETICS FOR ASSESSMENT OF METAL PARTITIONING DYNAMICS AT BIOINTERFACES

R.M. PRESENT, LIEC - Université de Lorraine - CNRS; E. Rotureau, CNRS UMR 7360 / Laboratoire interdisciplinaire des environnements continentaux LIEC CNRS UMR; P. Billard, LIEC   Université de Lorraine   CNRS; J.F. Duval, CNRS / Laboratoire interdisciplinaire des environnements continentaux LIEC CNRS UMR

Assessment of contaminants toxicity toward ecosystems requires the account of chemical species dynamics in solution as well as the integration of the various interfacial processes governing their partitioning and availability at biointerfaces, e.g. internalization, adsorption or excretion. In this work we present an experimental approach that allows the assessment of dynamic partitioning of metals (Cd(II)) at *Escherichia Coli* biointerfaces under poor-complexing medium conditions. The approach is based on the measurement and cautious analysis of Cd depletion kinetics in solution at various biocells number density. In-situ measurements of metal depletion kinetics in the presence of accumulating bacteria were performed with use of electroanalytical techniques. Two mutants of *Escherichia Coli* were selected for the experiments. Genetic mutations on one of the strains led to reduced metal excretion capacity. For the other strain, an additional mutation by plasmid introduction allowed the overexpression of metallothionein in the cytoplasm, which confers upon the bacteria an enhanced capacity to chelate metals in the intracellular volume. Data were quantitatively interpreted on the basis of a recent theory developed by Duval et al[1,2]. in order to quantify the kinetics and thermodynamics of the adsorption, internalization and excretion processes that govern the partitioning of Cd between intra and extra cellular compartments. Doing so, the relevance of the thermodynamic BLM framework could be rigorously evaluated for our system, which contrasts with many metal partitioning studies where the validity of BLM is *a priori* postulated without rigorous justification. **REFERENCES** 1. Understanding Cr biological fate in freshwater bivalves and identification of biomarkers

I. Aharchaou, LIEC; E. Battaglia, LIEC   Université de Lorraine   CNRS; H. Poirot, LRGP-CNRS-UL; M. PONS, LRGP-CNRS-UL / Laboratoire Réactions et Génie des Procédés; D.A. Vignati, CNRS / LIEC UMR

Chromium occurs in the environment mainly in two redox forms, namely Cr(III) and Cr(VI). These oxidation states have contrasting chemical and ecotoxicological features. Cr(VI) is of high ecotoxicological concern because it is readily absorbed into cells via the sulfate uptake pathways. Cr(III) is considered less harmful and the actual mechanisms of its internalization into cells are not well known. However, after entering into the cells, Cr(VI) is rapidly reduced to Cr(III) and only Cr(III) will possibly accumulate inside the cells. For this reason, it is desirable to compare accumulation and effects in biological organisms of the two chromium redox forms. Thus, In a first experiment acclimated specimen of the bivalve *Corbicula fluminea* were exposed to four concentrations (0, 5, 50 and 500μg/L) of either Cr(VI) or Cr(III) via the aqueous route for up to 96 h with renewal of exposure medium every 24 h. Bivalves were then dissected to isolate gills and digestive glands. These soft tissues were then digested and assayed for Cr content by ICP-MS. In a second experiment, organisms were exposed using the same protocol and dissected after 24h and 96h of exposure. Chromium content was measured as in experiment one and biomarkers of cellular damage, antioxidant, antitoxic defenses and energetic parameters were also assessed using a Konelab 20 Xti instrument after 24h and 96h of exposure. At 5μg/L, chromium bioaccumulation was comparable to Cr content in control organisms. At 50 μg/L, Cr(III) accumulated to similar levels in the gills and the digestive glands, while Cr(VI) preferentially accumulated in the gills. At 500μg/L, accumulated Cr concentrations were higher in the gills than in the digestive glands for both forms. While Cr(VI) concentration was stable in the exposure medium, total and filterable (0.22μm) Cr(III) concentrations decreased by more than 80% after 24 h. Results of biomarker expressions are currently being collected and elaborated.

MO165

The influence of co-contaminants on the bioavailability of arsenic, lead and cadmium

C. Ollson; E. Smith, University of South Australia; A. Juhasz, University of South Australia / Centre for Environm Risk Assessment   Remediation

Incidental ingestion of contaminated soil is often a major pathway for human exposure to inorganic contaminants. However, exposure is influenced by both biotic and abiotic factors that impact contaminant bioavailability. To date, bioavailability assessment of contaminated soil has focused on arsenic (As), cadmium (Cd) and lead (Pb), however, studies have typically assessed contaminant bioavailability individually, even when multiple elements are present in the same matrix. As a consequence, it is unclear whether interactions between these elements occur within the gastro-intestinal tract (GI tract) which impact absorption and bioavailability. In this study, As, Cd and Pb bioavailability was determined using an in vivo mouse model whereby mice (n = 12 per treatment) were exposed to the contaminant incorporated into AIN93G feed for 10 days. Initially, mice were exposed to each element individually, at three environmentally relevant concentrations; sodium arsenate (1, 5, 10 mg As kg^{-1}), Pb acetate (3, 15, 30 mg Pb kg^{-1}) and Cd chloride (0.2, 1, 2 mg Cd kg^{-1}). Subsequently, binary and tertiary elemental combinations were supplied to exhaust all possible combinations. Contaminant bioavailability was assessed by determining the concentration of As, Cd and Pb in target tissue (liver, kidney, femur) or excreta (urine, faeces). Contaminant relative bioavailability was also assessed in aged (12 years) spiked soils, using individual and tertiary elemental doses. When mice were exposed to As, Cd and Pb incorporated into AIN93G feed, the dose-response varied depending on the contaminant and endpoint assessed. However, for all elements, the dose-response was linear and did not differ significantly for single, binary or tertiary combinations. These results suggest that, at the concentration range tested, there was little or no influence on As, Cd or Pb absorption and bioavailability as a result of co-contaminant interactions. Similarly, when spiked soils were assessed, As, Cd and Pb relative bioavailability was consistent, irrespective of whether the soil contained single or tertiary elemental combinations. Moving forward, research in this area could investigate the potential of interaction occurring between these contaminants at a cellular level.

MO166

Effect of temperature on nickel biodynamics in Daphnia magna as determinated with stable isotope experiment

C.S. Pereira, GhEnToxLab; C. Janssen, University of Ghent / Laboratory of Environmental Toxicology and Aquatic Ecology GhEnToxLab unit; R. Blust, Department of Biology; K. De Schamphelaere, Ghent   University (UGent) / Laboratory for Environmental Toxicology and Aquatic Ecology GhEnToxLab unit

Temperature has a strong influence on the physiological state of ectothermic organisms like *Daphnia magna*. The physiological state of the organism can influence metal uptake, detoxification, sequestration and elimination and consequently metal toxicity. The information available about metal uptake rates in *Daphnia* is limited to studies with only one clone and organisms which were not acclimated prior to testing. An acclimation period is necessary in order to achieve the same performance across the different temperature treatments. The objective of the present study was to assess the effect of temperature on nickel uptake in four *D. magna* clones. The uptake of nickel was studied in four *Daphnia magna* clones at 15, 20 and 25°C. Four *D. magna* clones from the same natural population were acclimated during two generations to the temperature treatments. Nickel exposure concentrations were based on the 21 d 50% effect concentration on reproduction of the four *D. magna* clones at 15°C and 20°C, i.e. 50 and 70 μg Ni.L^{-1} respectively plus a control treatment. To determine uptake rates organisms five day old were exposed to the stable isotope ^{62}Ni during 72h and samples were collected at the time points 0, 8, 24, 48 and 72h. To avoid uptake via food organism were not fed during this period. Results showed that nickel body concentrations varied among the four *D. magna* clones. After 48h of exposure nickel concentrations in daphnia were lower at 25°C than at 15 and 20°C. A steady state was generally reached within 24h for all clones at 25°C in contrast with 15°C, which generally only reached a steady state after 48h of exposure.

MO167

Effect of aging on the toxicity of leached rare earth elements in soil over time

C. Fraser, J. Princz, Environment Canada / Biological Assessment and Standarization Section; R.P. Scroggins, Environment Canada / Biological Methods

Rare earth elements are increasingly becoming mined and used for various technological advances. As such, the risk assessments of new and existing products containing rare earth metals have been identified as a priority for the Government of Canada's Chemicals Management Plan. Particularly of interest, are soil effect data specific to boreal forested regions where metallic compounds can enter into the terrestrial environment through industrial emissions (e.g., metal smelting, mining, etc.), and ecotoxicological data are lacking. Given that boreal regions form a significant portion (~30%) of Canada's landmass, the effect of rare earth metals were evaluated on boreal species using boreal forest soils spiked with the test substance. To address the effect of leaching and aging on toxicity over time, tests were conducted by simulating deposition and weathering of two earth metals, lanthanum (La) and cerium (Ce), in reconstructed soil columns. Natural soil horizon stratification was maintained throughout the aging and leaching process. Subsequently, the toxicity of the aged soils were evaluated over time on plant growth (*Pinus banksiana*), as well as soil invertebrate reproduction (using the collembolan, *Proisotoma minuta*, and the earthworm, *Dendrodrilus rubidus*). The study was designed to mimic the natural environment, at which metal deposition might occur, with mobilization through the soil profile as as result of, for example, precipitation. The effect of the aging process on toxicity will be discussed, along with a discussion of metal availability by profile.

MO168

The importance of speciation in Chromium hazard and risk assessment

I. Aharchaou, LIEC; J. Py, Agence nationale de sécurité sanitaire Alimentation-Environnement-Travail; E. Battaglia, LIEC Université de Lorraine CNRS; S. Cambier, Luxembourg Institute of Science and Technology LIST / Environment and AgroBiotechnologies; J. Loizeau, Institut F.-A. Forel, University of Geneva; D.A. Vignati, CNRS / LIEC UMR

In aquatic environments, Chromium exists mainly in two redox forms, namely Cr(VI) and Cr(III). The role and the impact of Cr on the environment and living organisms depend on its chemical form. Cr(III) is considered much less ecotoxic compared to the hexavalent form of the same element. However, some recent studies report higher toxicity of Cr(III) than Cr(VI). Experimental verification of speciation during ecotoxicological tests can facilitate comparison among laboratory experiments or between laboratory and field situations. We used IC-ICP-MS to investigate possible conversion between Cr(VI) and Cr(III) in a standardized algal test medium (ISO8692) both in the absence and in the presence of the green alga *Pseudokirchneriella subcapitata*. Aliquots of test medium were spiked with 60 μg L^{-1} of Cr(III) or 115 μg L^{-1} of Cr(VI), corresponding to the EC50s at 72h determined in our laboratory for the two forms. No interconversions between the two redox forms were observed over 72h (i.e., the actual duration of the algal tests) either in the presence or absence of the algae. These results confirm that effects observed in the laboratory can be assigned with certainty to the specific redox form added to the test medium. However, filterable Cr concentrations in solutions spiked with Cr(III) were not stable over the experiment duration (72 hours). Considering that the total (unfiltered) Cr concentrations in the same solutions remained stable over 72 hours, we surmise that the observed decrease in filterable Cr concentrations was due to particle formation and not to Cr losses onto e.g. walls of the flask. Analysis of Cr(III)-spiked aliquots of test medium by Nanoparticle Tracking Analysis (NTA) confirmed that colloidal particles (approx. diameter 150 nm) quickly formed when Cr(III) was added to the medium. Particle diameter determined by NTA did not change with time even if filterable Cr concentrations measured during the experience decreased by 70%. Analogous Similar experiences experiments using Single particles Counting (SPC) system suggest that large particles accumulate in the solution with time, thus making sense of the observed decrease in filterable Cr concentrations.

MO169

Assessing bioavailability of soil arsenic using E. coli whole-cell bioreporters

Y. Yoon, Y. Kang, Y. Chae, S. Kim, Y. Lee, Konkuk University; S. Jeong, Kunsan National University / Dept of Environmental Engineering; Y. An, Konkuk University / Department of Environmental Heath Science

We determined the bioavailable arsenic in contaminated field soils before and after soil-washing processes to evaluate the arsenic removal efficiency using novel *E. coli* whole-cell bioreporters (WCBs). All of currently available arsenic bioreporters are based on arsenic responsive genes in *ars* operon, but we used gene in nickel responsive operon (*nik* operon in *E. coli*). Unlike other whole-cell bioreporters, the regulatory protein of *nik* operon, NikR, represses the transcription in the presence of Ni(II). Interestingly, when WCBs were exposed to eight heavy metals and metalloid, it responded only to As(III) exposure and showed the expression of reporter gene (*egfp*) under *nikA* promoter. Moreover, the response was proportional to a dose-dependent manner. Thus, this WCBs would be a genuine bioreporter to determine bioavailable arsenic quantitatively.

MO170

A meta-analysis on metal uptake kinetics and the relationship between metal accumulation and soil properties in soil organisms

M.M. Ardestani, Vrije Universiteit Amsterdam; N.M. van Straalen, Vrije Universiteit Amsterdam / Dept of Ecological Sciences; K. van Gestel, VU University Amsterdam / Ecological Science

Bioaccumulation can be a good indicator of the exposure of organisms to metal polluted soils. Metals are taken up from the aqueous phase of the soil (pore water) which is considered the main exposure route for most soil organisms. Metal bioaccumulation is a complex process that includes uptake, internal distribution, storage, and excretion. Toxicokinetics studies can provide a mechanistic understanding of the processes of uptake, elimination, and internal distribution of metals in soil organisms, and therefore also help unravelling the complex processes of metal bioavailability in soil. In this study, metal toxicokinetics in soil organisms and the relationships between metal bioaccumulation, metal exposure concentrations, and soil physical-chemical properties were investigated. We used data from the literature on terrestrial organisms such as earthworms, potworms, isopods, beetles, centipedes, snails, and collembolans. We summarized the uptake and elimination rate constants derived from bioaccumulation tests on different soil organisms. For all species and all metals, bioaccumulation followed a specific pattern which could be described by toxicokinetics models applied to calculate bioaccumulation parameters. Non-essential elements, such as cadmium and lead, generally accumulated in the soil invertebrates with relatively high uptake rate constants and most organisms were able to remove them from the body by excretion. For the essential elements, copper and zinc, internal concentrations remained quite constant for almost all test species. Among soil physical-chemical characteristics, soil pH, cation exchange capacity, clay and organic matter content significantly affected uptake rates of non-essential metals in soil invertebrates. For essential metals, kinetics was hardly influenced by soil properties, but rather prone to physiological regulation mechanisms of the organisms. Our analyses illustrated that toxicokinetics could be a valuable measurement to assess bioavailability of metals in soil.

MO171

Toxicokinetics and toxicodynamics of lead in Enchytraeus crypticus in soil

L. Zhang, VU University Amsterdam / Animal Ecology; K. van Gestel, VU University Amsterdam / Ecological Science

The present study aimed at investigating Pb uptake and elimination and toxicty in the potworm *Enchytraeus crypticus* in Lufa 2.2 natural soil. To assess Pb toxicodynamics and toxicokinetics, mortality and internal Pb concentrations were determined at different time intervals during the uptake phase of a toxicokinetics experiment. Body Pb concentrations were also measured at different time points after transfer of the animals to clean soil. To assess Pb availability, total, 0.01 M $CaCl_2$-extractable and pore-water Pb concentrations were measured in the test soil. A one-compartment model was used to describe the uptake and elimination kinetics of Pb in *E. crypticus*, while ultimate LC50 ($LC50_\infty$) and an elimination rate constant for effects of Pb on enchytraeid survival were estimated from the LC50-time relationship. Internal Pb concentrations increased with exposure time and reached steady state after around 7 d. In the elimination phase, body Pb concentrations decreased with time and reached equilibrium after around 4 d. For each Pb exposure concentration, potworm survival decreased with increasing exposure time. For each time interval, mortality of animals increased with increasing exposure concentration. $LC50_\infty$ was estimated to be 446 mg Pb/kg dry soil, which is lower than the 21-d LC50 of 558 Pb/kg dry soil, showing that the toxicity of Pb to *E. crypticus* expressed on total soil concentrations did not reach steady state within 21 d of exposure. LC50 expressed on the basis of internal concentrations in the surviving animals reached steady state within 14 d. It therefore seems that compared to Pb bioaccumulation, Pb toxicity is delayed in *E. crypticus*. The inert Pb fraction in the animals was estimated at 0.17, indicating that around 17% of the internal Pb could not be eliminated. The uptake rate constant was 0.14 g_{soil} g_{worm}^{-1} d^{-1}, and elimination rate constants were 0.96 d^{-1} (based on internal Pb concentration) and 0.046 d^{-1} (based on increasing toxicity with time), suggesting that approximately 5% of the internal Pb contributed to the observed toxic effects. Biological $t_{1/2}$ values for Pb elimination were calculated to be 0.72 d and 15.1 d for toxicokinetics and toxicodynamics, respectively, again indicating that development of toxicity with time was much slower than the uptake of Pb in *E. crypticus*.

MO172

Bioavailability and ecotoxicity of Cu substances to terrestrial organisms

J. Princz, H. Lemieux, C. Fraser, E. Ritchie, P. Boyd, Environment Canada / Biological Assessment and Standarization Section; C. Beer, D. Schwertfeger, Environment Canada / Biological Assessment and Standardization Section; R.P. Scroggins, Environment Canada / Biological Methods

The Government of Canada's Chemicals Management Plan (CMP) is an initiative created to quantify the environmental and human hazards associated with chemicals used in industry and commerce in Canada. Inorganic metal moieties are one group which has been identified as a CMP priority and form components of larger inorganic and organic substances. Given the volume of chemicals requiring evaluation under CMP initiatives, a metal moiety-based approach has been recommended to stream-line the risk assessment process. However, there is uncertainty over the effect of these moieties of concern to soil systems, and further still, whether other components of the substances (e.g., organic component in the case of organometals) to which they belon are of concern and elicit an effect. In order to assess a moiety-based approach, copper-containing substances, representative of broader groups were selected for ecotoxicity tests: water-soluble (copper sulfate) and water-insoluble (copper oxide) inorganic metals; a water-soluble organic metal salt (copper diethyldithiocarbamate); and water-soluble (copper D-gluconate) and water-insoluble (copper gluconate) organometals. Soil ecotoxicological studies were completed using standardized soil test methods to characterize effect on plant growth (*Trifolium pratense* and *Elymus lanceolatus*) and invertebrate survival and reproduction (*Folsomia candida* and *Eisenia andrei*). Soil chemical analyses were also conducted to evaulate for total metal, total parent compound (in the case of organic metal substances) and ionic activity.

MO173

Exploring the contribution of abiotic and biotic factors in elemental accumulation patterns in the shrew Crocidura russula exposed to air pollution

A. Sánchez-Chardi, Autonomous University of Barcelona / Microscopy Facility

Several biomarkers of exposure and effect have been checked in terrestrial small mammals (rodents and insectivores) inhabiting water and soil polluted sites, but less ecotoxicological information is available in air polluted sites. Moreover, the bioaccumulation patterns of abiotic and biotic factors that interact at "real world conditions" were understudied in small mammals. Here, the influence of abiotic (season) and biotic (age and sex) factors in the bioaccumulation patterns of 17 elements with ecotoxicological interest (Pb, Hg, Cd, Fe, Zn, Cu, Cr, Co, Mn, Mo, V, Ni, Sn, Sr, Ba, S, Se) was explored in soft tissues (liver, kidney, lung, heart, spleen, pelt) of Crocidura russula inhabiting a coal-fired power plant impacted area. The importance of the factors analysed was age>season>sex and the shrews from the polluted site showed highest concentrations of all elements in their tissues, specially Pb, Cd, Fe, Sn and Sr. Among tissues, heart and pelt were primary target tissues for accumulation of metals with toxicological interest such as Pb, Mo, V, and Ni. Differential exposure and detoxification response in shrews from polluted site also produced higher dispersion of data. Overall, the power station emissions increase the entrance and/or bioavailability of potentially toxic metals and non-metals in C. russula tissues that bioaccumulate depending on several biotic and abiotic factors. In conclusion, there is necessary the study of such factors to better interpret accumulation data of persistent pollutants and their toxic effects in natural populations.

MO174

Spatial variation of extractable elements in anoxic sediments from the Oslofjord (Norway) and the Gulf of Gdańsk (Poland)

T. Ciesielski, Norwegian University of Science and Technology / Dept of Biology; A. Wiese, Medical University of Gdansk; G. Kowalewska, M. Szymczak-Żyła, A. Filipkowska, L. Lubecki, Institute of Oceanology PAN; T. Bączek, Medical University of Gdansk / Department of Pharmaceutical Chemistry; G.D. Breedveld, Norwegian Geotechnical Institute; A.M. Oen, Norwegian Geotechnical Inst. / Dept Environmental Engineering; B. Jenssen, Norwegian University of Science and Technology / Biology; M.V. Ardelan, Norwegian University of Science and Technology

The distribution of the extractable forms of elements was compared in recently sedimented matter from the Oslofjord (Norway) and the Gulf of Gdansk (Poland). Short sediment cores (20 cm long) were collected at 12 stations, 6 from the Oslofjord and 6 from the Gulf of Gdansk. The sediment samples were analyzed for 62 chemical elements applying the BCR sequential extraction procedure and high resolution inductively coupled plasma mass spectrometry (HR-ICP-MS). Certified reference material (BCR-701, fresh water sediments for sequential extraction) was used for the estimation of the procedure efficiency. Moreover, organic carbon, total nitrogen, stable carbon and nitrogen isotopic composition ($\delta^{13}C$ and $\delta^{15}N$), grain size, ^{210}Pb activity and pigments, were determined in the samples. Spatial distribution of the elements was analyzed with principal component analysis (PCA). Finally, the environmental quality of the sediments was evaluated with contamination factor (Cf), pollution load index (PLI) and risk assessment code (RAC). Multivariate analysis (PCA) separated samples from Norwegian fjord and Gdansk Bay. The most significant component was characterized by high loading values of rare earth elements (REE), that can be explained by metamorphic origin of the Oslofjord bedrock. Relatively high proportion of trace elements Cd, Mn, Pb and Zn were found in the acetic acid soluble extract fraction. This indicates presence of exchangeable, weakly bound forms of these elements, prone to be bioavailable to benthic organisms. On the other hand, Cr, Fe and Ni were found mostly in the residual fraction of the sediments indicating their low mobility and low susceptibility to be released from the sediments. The Cf showed that all locations were contaminated by Cd and Mn with highest values of Cf in the innermost part of Oslofjord (Bunnefjord), where the deeper-water exchange is restricted. This was confirmed by PLI – the highest values of PLI was also found for station located at Bunnefjord. According to RAC, sediments in Bunnefjord and at a station located in a deepest part of Gdansk Bay (Gdansk Depth) were classified as constituting 'very high ecological risk' due to high concentration of Mn in weakly bound acid soluble fraction of sediments. This indicates the potential of Mn to be a threat to local ecosystem ability of this heavy metal to enter food web. High and moderate risks were estimated for Sb and As respectively.

MO175

Scenario analysis of metal fate in estuaries

A. de Souza Machado, Leibniz Institute of Freshwater Ecology and Inland Fisheries / Ecophysiology and Aquaculture; M. Toffolon, University of Trento / Department of Civil Environmental and Mechanical Engineering; C. Zarfl, University of Tuebingen / Center for Applied Geosciences; K. Spencer, Queen Mary University of London / School of Geography; L. Sittoni, K. Cronin, DELTARES

Estuaries provide a multitude of ecosystem services such as drinking water supply and water purification. Therefore, estuarine areas have been zones of intense human occupation and industrialisation, with a legacy of historic and current metal contamination. Due to the accumulation of fine-grained sediments, estuaries are sinks for heavy metals which may be problematic pollutants due to their environmental persistence and potential toxicity. Additionally, coastal systems are facing threats associated with climate change that may affect metal mobilization. For example, dredging and coastal squeeze may result in the re-working of tidal flat sediments, while annual river discharge may change (decrease in summer, increase in winter) due to climatic shifts. Such effects will interact with tides and baroclinic circulation and thus determine heavy metal distribution in future estuaries. The present study uses the 3D hydrodynamic model Delft3D-FLOW fully integrated with the water quality model Delft3D-WAQ to investigate environmental dynamics, metal partitioning and metal fate (during 1-year period) in an idealized estuary (funnel-shaped). This model was scaled so that processes could be representative of alluvial systems as the Thames Estuary (London, UK). Simulations were run for Cd, Cu, Fe and Pb under three morphological scenarios (natural tidal flats, moderate coastal squeeze, severe coastal squeeze), three discharge conditions (low, medium, high), and a tidal amplitude of 4 m in comparison to no tide. The results highlight that tidal flats play a significant role in the dynamics of dissolved and particulate metals. Similarly, river discharge and the position of salinity front jointly caused non-conservative metal behaviour. This study underlines the sensitivity of metal partitioning and residence time of contaminants to the abundance of tidal flats, and thus indicates that river-dominated tidal estuaries require these environments to achieve good biogeochemical functions on water purification.

The effect of environmental conditions on the bioavailability of metals from contaminated sediment

J.I. Jones, QMUL / School of Biological and Chemical Sciences; F.T. O'Shea, Queen Mary University of London / School of Geography; J.F. Murphy, Queen Mary University of London / School of Biological and Chemical Sciences; K. Spencer, Queen Mary University of London / School of Geography; P. Rainbow, The Natural History Museum / Dept of Zoology; A.L. Collins, Rothamsted Research, North Wyke; A. Moorhouse, the Coal Authority; V. Aguilera, DEFRA; P. Edwards, Southern Illinois University Carbondale / Zoolog; F. Parsonage, DEFRA; H. Potter, Environment Agency; P. Whitehouse, Environment Agency / Evidence

Abandoned metal mines have left a legacy of sediments contaminated with metals. These sediments may constrain the achievement of the targets set out by the EU Water Framework Directive. A cost-effective approach to dealing with sediments contaminated by metal mining activities should be based on an understanding of how environmental conditions influence bioavailabilty, and hence the conditions under which they present a risk to achieving Good Ecological Status. Here we

have undertaken a controlled laboratory experiment in replicated mesocosms, where we have incubated a field-relevant biomonitor species (*Baetis* spp. mayflies) with sediment collected from a river impacted by an abandoned copper mine. The water (conductivity approx. 40 µS) and *Baetis* were collected from an independent control site of similar geology but not impacted by metal mining. The mesocosms were manipulated to provide three levels of sediment organic matter, three levels of water hardness, and two levels of resuspension, in a fully factorial design. The body burden of metals in *Baetis* was used as a measure of the bioavailability of metals under the experimental treatments. Once set up the mesocosms were incubated at 10 °C for three weeks, for the sediment and water to equilibrate. After this initialequilibration period, a sample of the sediment was collected from each mesocosm for determination of particle size distribution, organic carbon content, and Fe oxides. After the initial equilibration period, the sediment in those replicates to be resuspended was disturbed and allowed to settle. Then 20 individuals of the biomonitor species (*Baetis*) were added and the experimental incubation period began. After incubation for four weeks, the body burden of metals in the *Baetis* was determined using a Vista-Pro CCD Simultaneous ICPOES. At the end of the experiment a second sample of sediment was collected for characterisation as above. Data were analysed using generalized linear models, to establish the effect of the experimental treatments, and any interactions among them, on the body burden of trace metals in *Baetis*: our measure of the bioavailability of metals in the experimental mesocosms.

A turbidity current plume model for submarine tailing disposal on sloped terrain: providing data for risk assessment of the exposure to pelagic organisms

J. Skancke, SINTEF / Monitoring and Modelling; R. Nepstad, SINTEF Materials and Chemistry / Monitoring and Modelling; E.J. Davies, SINTEF Materials and Chemistry / Oil Spill Research; T. Nordam, SINTEF Materials and Chemistry / Monitoring and Modelling; B. Hansen, J. Farkas, SINTEF Materials and Chemistry; D. Altin, BioTrix; A. Booth, SINTEF Materials and Chemistry / Environmental Technology; T. Nordtug, SINTEF Materials & Chemistry / Applied Environmental Biology and Chemistry; A. Olsen, Norwegian University of Science and Technology; I.B. Øverjordet, SINTEF Materials and Chemistry / Enviornmental Technology; . Johansen, SINTEF Materials and Chemistry

Submarine and coastal shallow-water disposal of mine tailings has the potential to spread toxic metal into the aquatic environment. However, the extent of spreading, and therefore also the risk of exposure, depends greatly on the initial conditions of the release: the composition of the slurry, the discharge rate, and the depth and bathymetry around the discharge area. Computer modelling of the disposal plume that takes into account these initial conditions has the ability to predict the transport both to the sea bed and the transport of dispersed matter from the plume in the water column. Therefore, computer modelling of the release can estimate the degree of exposure to pelagic and benthic organisms from mining discharges. Plume calculations in the DREAM model currently handle discharges onto a flat sea bed, taking into account radial spreading and the angle of repose of the deposited matter. However, submarine discharges may be placed on sloped terrain, for example in deep fjords, where the release will cause a turbidity current that will settle according to the bathymetry in the discharge area. Here, we present improvements to the DREAM model to handle density currents by taking into account the bathymetry around the release site. Our approach is to calculate the bathymetric gradient, and simulate the spreading of the turbidity current along the resulting plane, using an estimated roughness to infer friction supplied by the sloping terrain. By applying the improved model to areas of ongoing tailing disposal, we will use the resulting water column concentrations to inform risk assessments of the exposure of metals to pelagic organisms.

MO178

Influence of humic acids on the bioavailability of metals in sediment samples from the Berg River Catchment, South Africa

V.S. Somerset, CSIR South Africa / NRE; U. Skepe, University of the Western Cape South Africa / Chemistry; B. Silwana, C. Van der Horst, E. Iwuoha, University of The Western Cape / SensorLab Department of Chemistry; C. Walters, CSIR / Natural Resources and the Environment

Heavy metals in the environment pose serious human health risks, since some of these metals such as lead; mercury and cadmium are highly toxic even at trace amounts. Humic acids are known to be heterogeneous compounds containing mostly carboxyl and phenolic hydroxyl functional groups, providing these organic macromolecules with an important role to play in the transport, bioavailability and solubility of heavy metals in the ecosystem. Humic substances refer to a category of naturally occurring organic materials found in soils, sediment and natural waters. Humic acids are further known to be insoluble in water under acidic conditions, but tend to be more soluble at higher pH values, where they can also be extracted [1-2]. It is known that heavy metals in soil solutions are mostly bound in complexes with low molecular weight organic acids (LMWOA) [3]. The occurrence of these complexes is strongly dependent on pH and some of these complexes formed between heavy metals and LMWOA can be detected with analytical techniques. The work covered in this study is twofold of nature and investigated: (i) firstly, the influence of humic acids on the bioavailability of metals in freshwater sediments; (ii) secondly, the use of spectroscopic analysis to determine the metals in the bioavailable fractions. The different fractions obtained for the use of different humic acids were analysed using inductively coupled plasma atomic emission spectroscopy (ICP-AES) and the concentrations of lead (Pb), nickel (Ni) and copper (Cu) were found to be different in each fraction. The results obtained for the bioavailability of Cd(II), Pb(II) and Ni(II) concentrations in the sediments, have shown that the concentrations obtained at different sampling sites was a function of the organic content, chloride and sulphate concentration. Other seasonal and sampling site physico-chemical conditions also influenced the metal bioavailability in the sediment samples. **Keywords**: Humic acids; heavy metals; sequential extraction; bioavailability; sediments; voltammetry; stripping analysis; Berg River **References** [1] Rahman et al. Past and present platinum contamination of a major European fluvial-estuarine system: insights from river sediments and estuarine oysters

M. Abdou, UMR5805 EPOC / Geochemistry; J. Schäfer, Université de Bordeaux; A. Cobelo-García, P. Neira, CSIC / IIM; J. Petit, Université de Bordeaux; D. Auger, J. Chiffoleau, IFREMER; G. Blanc, Université de Bordeaux

With their massive use in modern societies, Technology-Critical Elements (TCE) are widely dispersed in natural environments requiring a deeper understanding of their environmental impact and cycling in the biosphere. Among these elements Platinum Group Metals (PGM) are modern, technology relevant elements for which the anthropogenic cycle has outcompeted the natural cycles. Stripping voltammetry was used for accurate determinations of platinum (Pt) in historical records of river sediments (dated from 1952 to 2001) and estuarine wild oysters (collected from 1981 to 2013) from the Gironde fluvial-estuarine continuum (SW France) comprising the Lot River. The chronicled samples displayed Pt concentration variations with i) sediment cores from the Lot River showing Thorium (Th) - normalized Pt concentrations up to $11.10^{-5} \pm 0.79.10^{-5}$ for the deepest part of the core which is 5 times higher than the regional geochemical background value (Pt/Th ~ $1.9.10^{-5} \pm 0.39.10^{-5}$) and ii) wild oysters from the Gironde Estuary mouth with Pt concentrations between 0.80 ± 0.01 pmol.g^{-1} and 3.10 ± 0.14 pmol.g^{-1}. These variations reveal the evolution of Pt pressure in this ecosystem with past Pt contamination of sediment cores reflecting the former industrial (smelter) activities in the Lot River watershed and wild oysters having recorded the phasing-out of the smelter-related historical Pt contamination and the recent rise of a new source of Pt to the system. With the application of an empirical model, recent temporal variations of oyster samples were attributed to the extensive increase of Pt demand for car catalytic converters, pointing towards the increasing importance of this emerging source to the aquatic system. These results suggest that anthropogenic vehicle-derived Pt emissions may profoundly affect the Pt budget of the watershed and induce Pt uptake by organisms such as wild oysters that prove to be sensitive biomonitors for Pt contamination over the time. Furthermore this study showed that oysters may bioconcentrate Pt (Bioconcentration Factor, BCF ~ 10^3) and potentially transfer this metal contamination to the higher food chain. Ecotoxicological impacts of such rapid, significant change in the Pt use in industrial applications and its subsequent introduction to the environment are yet still widely unknown and need to be further investigated to complete our knowledge on environmental Pt contamination, processes and possible adverse effects to biota.

MO180

Thallium pollution in Tuscany, Italy: a non-invasive population-based control study

E. BRAMANTI, Italian National Research Council; B. Campanella, University of Pisa; M. Onor, A. D'Ulivo, Italian National Research Council; M. D'Orazio, R. Giannecchini, R. Petrini, University of Pisa

Here we report the results of a non-invasive population-based study that aimed to quantify Tl levels in 150 urine and 297 hair samples from the population of Valdicastello Carducci and Pietrasanta, Italy. A recent study shown indeed the presence of thallium (Tl) at concentrations of concern in groundwaters near Valdicastello Carducci (Italy). Tl contamination was also found in water intended for human consumption distributed in the same area, where it reaches 9 mg/L Our study aimed to i) quantify Tl with non-invasive sampling procedures; ii) correlate Tl levels found in hair and urine with Tl concentration in the tap waters used by inhabitants; iii) exploit the suitability of saliva as alternative matrix for environmental exposure studies. Tl values found in urine and hair samples were correlated with Tl concentration levels found in tap water in the living area of each citizen and with his/her habits. Tl concentration is higher than 0.6 µg/L and 20 ng/g in about 50% of urine and hair samples, respectively. As Tl is generally removed from the body via urine, the high concentrations of Tl in the biological samples of the studied area must be ascribed to high accumulation of Tl through the food chain. The kinetics of decay of Tl concentration in urine samples was also investigated, finding that even 60 days after the end of the exposition, mean Tl urinary concentration was still extremely high. Our findings indicate that

people resident in the contaminated area significantly accumulated thallium in their urine and hair compared to the reference values of Italian population.

MO181

Uptake and potential acute and physical effects of barite on the pelagic zooplankton Calanus finmarchicus (Crustacea: Copepoda).

B. Hansen, SINTEF Materials and Chemistry / Environmental Technology; C.Y. Bådsvik, Norwegian University of Science and Technology, N-7491 Trondheim, Norway; D. Altin, BioTrix; T. Nordtug, SINTEF Materials & Chemistry / Applied Environmental Biology and Chemistry; A.J. Olsen, Norwegian University of Science and Technology, N-7491 Trondheim, Norway / Department of Biology

Drilling muds used for offshore oil drilling operations contain weighting particles like barite. The present work involved assessing barite uptake and acute (lethality) and physical (sinking speed) effects of barite-containing drilling mud on *Calanus finmarchicus*. This species is by far the dominating zooplankton species in the Northern Atlantic, and these copepods were treated with an environmentally realistic (10 ppm) concentration of drilling mud up to 168 hrs followed by 100 hrs of recovery. Species were sampled several times during the experimental period, and both microscopic photographs and metal analyses confirmed uptake and accumulation of barite and co-uptake of other metals (e.g. silicon and aluminium). Acute toxicity was assessed, but an LC_{50} was not determined within the range 5-320 ppm. Physical effects of drilling mud on the neutral buoyancy of copepods were assessed by measuring sinking speed of sedated copepods. The main conclusions from this investigation were that i) copepods do in fact filter and ingest mud particles, ii) barite does not appear to have acutely toxic effects, iii) barite particles are withheld within the gut for longer than 100 hrs recovery in clean sea water even though the extractable amounts of Ba, Si and Al were somewhat reduced after recovery, and finally iv) at environmentally realistic concentration ingestion of barite particles affect copepod buoyancy.

Potential impacts of mine tailing plumes on pelagic filter-feeders

B. Hansen, SINTEF Materials and Chemistry / Environmental Technology; J. Farkas, SINTEF Materials and Chemistry / Applied Environmental Biology and Chemistry; D. Altin, BioTrix; E.J. Davies, SINTEF Materials and Chemistry / Oil Spill Research; R. Nepstad, SINTEF Materials and Chemistry / Monitoring and Modelling; A. Booth, SINTEF Materials and Chemistry / Environmental Technology; J. Skancke, SINTEF Materials and Chemistry / Monitoring and Modelling; T. Nordtug, SINTEF Materials & Chemistry / Applied Environmental Biology and Chemistry; A.J. Olsen, Norwegian University of Science and Technology, N-7491 Trondheim, Norway / Department of Biology; I.B. Øverjordet, SINTEF Materials and Chemistry / Applied Environmental Biology and Chemistry

Deposition of mine tailings in fjords along the Norwegian coast is known to have ecological implications for benthic fauna, but little information is available on the potential impacts on pelagic organisms. Depending on local hydrology, release of tailings can result in plumes where the particle size distribution may extend into the sub-micron range. Whilst the bulk of tailings will settle on the sea floor close to the release point, the sub-micron fraction is likely to remain suspended for longer time periods and for spreading to more extensive. Calanoid copepods, such as *Calanus finmarchicus*, are important pelagic filter-feeders serving as a crucial link in the food chain between primary producers and fish. They are ubiquitously distributed in the Northern Atlantic including fjord systems in Norway. Their impressive capacity for filtering particles for food suggests that they will readily ingest mine tailing particulates, with subsequent exposure to metal-bearing particles and dissolvable metal ions originating from the tailings. We report experimental data for the purpose of environmental risk assessment of mine tailing deposits in Norwegian fiords, where the acquired data will be used to inform risk models. The physicochemical properties of the mine tailing fraction remaining suspended in seawater for an extended period (e.g. 10 d) is comprehensively characterised (composition and particle size distribution). Copepod filtration rates will be determined for different size fractions of particulate matter, sensitivity of copepods to specific elements in the particulate and dissolved phase, and uptake and depuration rates of those elements. Further, the influence of floatation and flocculation chemicals used in mining processes on particle and element bioavailability and potential toxicity will be studied. Finally, we will determine potential implications of environmentally realistic exposures (particle size distributions and concentrations) to mine tailings on copepod survival, growth and reproduction. Environmentally realistic exposure experiments will be designed based on data from field surveys in fjords with active submarine tailing depositions using state-of-the-art in-situ particle imaging systems.

MO183

Determining the removal of platinum group metals in industrial effluent during sewage treatment

E. Stutt, WCA Environment Limited; I. Wilson, G. Merrington, WCA Environment; K. Rothenbacher, European Precious Metals Federation

Exposure assessment of metallic substances in industrial effluent discharged to freshwater via sewage treatment plants (STPs) requires knowledge of the retention of the metals during sewage treatment. No information could be identified in the scientific literature on the removal efficiency of municipal STPs processing industrial effluent containing platinum group metals (PGMs). A monitoring study was therefore undertaken to measure the removal of PGMs (platinum, palladium, rhodium and ruthenium) at a number of STPs in order to inform the chemical safety assessment of PGM substances for REACH registration. The removal efficiency for metals during sewage treatment depends upon a number of factors including the sorption characteristics of the metal, the treatment technology applied at the STP and the plant's retention time, which varies according to rainfall and flow rate. A monitoring study was undertaken at three STPs across Europe known to receive effluent containing PGMs. PGMs concentrations (total and dissolved) were measured in influent, effluent and sludge. Analysis was also undertaken for parameters such as pH, alkalinity, hardness and the concentration of total suspended solids. Preliminary analysis of the results indicates differing removal efficiency for the individual PGMs and significant temporal variation at the STPs study sites which is likely to be due to differences in retention time caused by changes in rainfall.

MO184

Use of ombrotrophic peatlands for the assessment of retrospective spatial pollution from atmospheric deposition

I. Twardowska, Polish Academy of Sciences / Institute of Environmental Engineering; E. Steinnes, Norwegian University of Science and Technology (NTNU), Trondheim / Department of Chemistry; E. Miszczak, Polish Academy of Sciences / Institite of Environmental Engineering Zabrze; S. Stefaniak, Polish Academy of Sciences / Institute of Environmental Engineering Zabrze

The use of ombrotrophic peatlands as a tool for retrospective quantitative identification of spatial pollution from dry and wet deposition of airborne elements was investigated within the study on the **development of integrated geophysical/ geochemical methods of soil pollution assessment in problematic areas. The study was conducted in Norway and Poland, where six peat bogs in different areas were selected within the possible long-range transport (LRTP) pathways from diverse sources.** From the selected bogs, peat cores were taken, and a comparative analysis of 36 elements was performed along the vertical profiles in layers 3-5 cm thick. Of these, 15 airborne trace elements – proven long range migrants –enriched surface layer of the studied pit bogs to the highest extent. The data showed high correlation with possible emission sources and supplied precise geochemical data related exclusively to the LRTP and element dry and wet deposition. Of the studied sites, N-Sv indicated the highest spatial pollution with Ni (501-716 mgNi/g) and Cu (273-580 mgCu/g). The character of pollution and its concentration in the uppermost 0-3 cm layer unequivocally points to the nickel smelting plant located abroad at the North as a strong contemporary source of these elements. In another peatbog N-Gy at the S of Norway, highly elevated concentrations of practically all airborne elements, with a maximum in the layers 5-10 cm, indicates older LRTP from many sources, which is in **a good agreement with the emission levels in Europe in XXth century, along with the directions of LRTP. In turn, the peat bog P-Iz (Poland) revealed high pollution with Pb, Zn, Hg and As in the layer 10-14 cm. Other sites (P-Wg and N-Mo) i**ndicated temporal pollution from several recent sources, in P-Wg from stronger, and in N-Mo from moderate ones. The samples were dated by the ^{14}C and ^{210}Pb isotope methods indicating the time period of contaminant deposition. The study endorsed peat bogs as reliable tools for quantitative retrospective assessment of LRTP impact, in particular for evaluation of temporal atmospheric deposition of airborne pollutants, comparison of deposition rates in different geographical locations and for estimation of LRTP between different geographic areas. This study has received funding from the Polish-Norwegian Research programme operated by the National Centre for R&D under the Norwegian Financial mechanism 2009-2014 in the framework of Project Contract No. Pol-Nor/199338/45/2013

MO185

High Level Radio-Cesium Pollution in Street Dust Samples Collected in the Vast Area of Eastern Japan and The Probability as a Supply Source to River Systems

H. OZAKI, Tokyo University of Agriculture and Technology / Center for Higher Educational Development; H. TAKAHASHI, C. WATAI, R. INAMOCHI, T. NAGASHIMA, Tokyo University of Agriculture and Technology / Dept Environmental Sci Biosphere; T. GOMI, Tokyo University of Agriculture and Technology / ept International Environmental and Agricultural Science; I. WATANABE, Tokyo University of Agriculture and Technology / Department of Environmental Science on Biosphere

1. Introduction The accident of Fukushima Daiich Nuclear Power Plant (FDNPP) caused severe pollution of radionuclides in Japan. It has been elucidated that significantly higher ^{137}Cs concentrations were found in the litter layer in forests and particle-adsorbed 137Cs is gradually discharged to oceans though rivers. Street dust has been focused for its high concentrations of heavy metals and other anthropogenic compounds. On the other hand, ^{137}Cs level in street dust is not well-known. **2. Materials and methods** Street dust samples were collected from 69 locations within 6.5-240 km from FDNPP in 2013 and 2014. The ^{137}Cs concentration was determined by high-purity germanium semiconductor detector after drying and sieving (< 0.2mm). **3. Results and discussion 3.1. Spatial**

distribution ^{137}Cs concentration in street dust was the highest at 7.6km south (503,000 Bq/kg) and decreased with distance from FDNPP. The higher ^{137}Cs concentrations were shown in the north-west and south followed by north and west in the137Cs concentrations in the 50-150km area revealed south > northwest and southwest > north and west whereas the northeast of Tokyo and the northern part of Gumma Prefecture specifically indicated higher anomaly beyond 150km. The spatial distribution is very consistent with the diffusion path of the radioactive plume estimated by SPEEDI and results of locally conducted on-site monitoring of atmospheric deposition. **3.2. Comparison of ^{137}Cs level with soils and sediments** ^{137}Cs concentrations in street dusts were significantly higher than those in top soils (< 5cm) of forest, paddy, crop, fruits and grassland fields collected in the p< 0.05) ^{137}Cs has been detected in estuarine and bay sediments, and street effluent is a known source of heavy metals entering neighboring water catchment area. These facts indicate a possible washout of ^{137}Cs from street to aquatic ecosystem. **4. Conclusion** Street dust contains high concentrations of ^{137}Cs transported by the radioactive plume. Therefore street dust is an effective media to analyze ^{137}Cs pollution and a probable channel for ^{137}Cs to migrate from land to ocean. It may play a considerable role in elucidating ^{137}Cs dynamics in environment. **Acknowledgement**: We would express our appreciation to the local NPO Corporation and financial support by JSPS KAKENHI (No. 26870180).

Heavy metal Bio-accumulation in different tissues of Euryglossa orientalis, Chirocentrus nudus and sediments in Bahrekan Bay (The Northwest of Persian Gulf)

M.M. Rouzbahani, Islamic Azad University / Department of Environmental Science; A. Harirforoush,

Concentration of Ni, V, Pb and Cu were determined in bottom sediment and liver, gills and fillet of *Euryglossa orientalis and Chirocentrus nudus* along the Bahrekan Bay in the Northwest of Persian Gulf in Iran. Sediment samples and fish species were collected during winter 2013 and spring 2014. Heavy metal analysis was performed by Atomic Absorption Spectrophotometer. Results showed that mean concentrations of heavy metals were high in liver and gills of *Euryglossa orientali*. Also heavy metals had the most accumulation in liver of *Euryglossa orientali*. Target tissue for accumulation Ni,V,Cu and Pb are gills and liver in *E. orientali* and *C. nudus* . In tissues of two fish species fillet has the minimum concentration level of trace elements. The concentrations of heavy metals were lower than legal limits in the fillet (edible part), except for Pb that was higher than permitted limits that is a negative point for consumption by human. Bioaccumulation factors (BAFs) were determined for different tissues of fish species with respect to elemental concentrations in sediment. BAFs results indicated that all BAFs in liver are more than gills and then more than fillet. Also BAF of Cu in liver and gills of k is more than 1.

Toxicity Testing in Sediments - Bioassays As Link Between Chemistry and Complex Benthic Community Testing for Sediment Quality Assessment (P)

MO187

Assessing the predictive ability of Sediment Quality Guidelines (SQG) for fine sediments by using a pollution-sensitive biotic indicator

M. Brinke, Federal Institute of Hydrology / Biochemistry and Ecotoxicology; S. Höss, Ecossa; E. Claus, C. Möhlenkamp, G. Reifferscheid, Federal Institute of Hydrology / Department Biochemistry and Ecotoxicology; W. Traunspurger, University of Bielefeld / Department of Animal Ecology; P. Heininger, Federal Institute of Hydrology / Division Qualitative Hydrology

Fine sediments are often associated with pollution, because they are a major binding phase for many substances inside waterbodies. The appropriate management of polluted fine sediments, whether concerning, for example, dredging activities or river management plans, is thus an important issue. For prioritization of further assessment or management options for fine sediments, we have developed Sediment Quality Guidelines (SQG) that are based on endobenthic organisms living between fine sediment particles throughout their whole life cycle (Nematoda). Specifically, we first derived Threshold Effect Concentrations (TEC) and Probable Effect Concentrations (PEC) for 40 single substances and 4 sum parameters. Then, for quantification of the toxic potential and subsequent classification of a sediment sample, an index based on the PECs and the corresponding measured concentrations of the sample can be calculated (mean PEC-Q). However, validation of the predictive ability of the index is crucial and thus, we used and independent data set consisting of simultaneously analysed chemical and biological (nematode community) information for this purpose. For each sample of the data set, mean PEC-Q as well as the NemaSPEAR[%]-index (Nematode SPEcies At Risk), which indicates pollution-induced nematode community alterations (Höss et al., 2011, Environ. Int. 37: 940-949), were calculated. The results clearly showed a decrease of the NemaSPEAR[%]-index, i.e. a loss of pollution-sensitive species, with increasing mean PEC-Q. However, the correlation is unsurprisingly not a total one and in specific sediments false-negative and false-positive indications might occur (e.g., due to lower or higher bioavailability of some substances or confounding factors influencing the NemaSPEAR[%]-index). Thus, we finally transformed the correlation of the two indices into "incidences of toxicity" (MacDonald et al., 2011, Arch. Environ. Con. Tox. 39: 20-31), from which the probability of toxicity for a specific mean PEC-Q can be deduced. Specifying the probability of toxicity instead of the mere exceedance or not exceedance of a fixed threshold value likely yields valuable information for risk managers and regulators.

Toxicity screening of sediments from Lake Geneva using the freshwater ostracod Heterocypris incongruens (ISO 14371).

M. Casado-Martinez, Centre Ecotox; T. Benejam, Swiss Centre for Applied Ecotoxicology; J. Loizeau, Institut F.-A. Forel, University of Geneva; I. Werner, Swiss Centre for Applied Ecotoxicology / Department of Anatomy Physiology and Cell Biology; B. Ferrari, Ecotox Centre CH

Lake Geneva is the largest water body of freshwater in Western Europe, draining a watershed of about 8000 km^2 in Switzerland and France with the Rhone being its major tributary. Lake Geneva is subject to anthropogenic pressures due to a large population, agriculture, and industries, and is periodically monitored for contaminant concentrations in water, sediment and biota [Loizeau et al. 2013]. The last monitoring campaign addressing sediment quality of the whole lake dated back to 1988 and addressed mainly metal and nutrient concentrations in sediments [Arbouille et al. 1989]. More recent studies on the zoobenthos have shown a significant improvement of the quality of sediments over the past twenty years [Lods-Crozet & Reymond 2006]. In 2015, a large sampling campaign supported by CIPEL (International Commission for Lake Geneva Protection) was carried out to provide a comprehensive assessment of micropollutant concentrations in sediments and zoobenthos. We will present the results of testing thirty sediment samples collected from the whole lake, with a sediment-contact test using the freshwater ostracod *Heterocypris incongruens* [ISO 14371-2012]. This test offers many advantages over other traditional sediment-contact tests such as requiring a small sample volume and the possibility to obtain test organisms from cysts then culturing is not needed. Despite the relatively long test duration (6 days) it is a promising method for screening the ecotoxicological quality of freshwater sediments. A preliminary analysis of the results allowed the mapping of the ecotoxicological quality of the sediment, which ranged from no or slightly toxic to highly toxic. We will discuss both the ecotoxicological quality of sediments from Lake Geneva and the performance of this test system. Arbouille D, Howa H, Span D, Vernet JP. 1989. Etude général de la pollution par les métaux et répartition des nutriments dans les sédiments du Léman. Rapp Comm int prot eaux Léman contro pollut, Campagne 1988 : 189-172. ISO 14371-2012. Implications of freezing sediments for use in ecotoxicological testing under static conditions

C. Borel, IDYST; J. Peña, L. Monbaron, University of Lausanne / Faculty of Geosciences and Environment; B. Ferrari, Ecotox Centre CH; N. Chevre, Université de Lausanne / Faculty of Geosciences and Environment

Laboratory-based ecotoxicological approaches for testing sediments often require the use of field samples that have been stored frozen. However, freezing is expected to change the biogeochemical characteristics of the sediment, which in turn may modify the bioavailability of contaminants and thus, the biological responses of the exposed organisms. Therefore, sediment freezing may lead to biased extrapolation of results to environmental conditions. In this study, we monitored over a period of one month the chemical behavior of 1 L static microcosms containing freshly sampled sediment versus the same sediment stored frozen. The results showed that the pH increased differently in the water column during the first 17 days of the experiment, and then reached a similar level in both microcosm types until the end of the experiment. The nitrogen cycle monitored in the overlying water was slower and more intense with the frozen sediment than with the fresh sediment. Toxic species NH4+, NH3 and NO2- were present until day 14 in the water column of the frozen sediment, whereas they were only present until day 4 in the fresh sediment. The concentrations of the N-compounds were close to the toxic threshold values for pelagic and benthic organisms in the frozen sediment microcosms. We thus assume that higher concentrations, i.e. above ecotoxicological threshold, might be reached with sediment containing high biotic activity or if food for the exposed organisms is added to the microcosm. Finally, as expected most of the biota in the frozen sediment died during the freezing period; only bacterial colonies and cyanobacteria grew on the sediment during the experiment. Cyanobacteria, which are known to produce toxins, expanded dramatically between day 14 and 21. In conclusion, we do not recommend stored-frozen sediment for ecotoxicological testing of pollutants under static conditions. However, for method development or bioavailability experiments, when the complexity of natural sediment and experiments need to be conducted over several months, stored-frozen sediment can be used with a minimum conditioning period of 10 to 14 days before introducing the test organisms. For the fresh sediment microcosms, we recommend a 7 days conditioning period before introducing the test organisms. Finally, sediment storage and conditioning should be considered when developing standardized ecotoxicological procedures.

MO190

In vitro screening for steroid endocrine disruptive and Ethoxyresorufin-O-deethylase (EROD) inducing activity in surface sediments from Mar Menor lagoon (SE Spain)

C. Martinez-Gomez, Instituto Español de Oceanografia / Marine Contamination and Biological Effects; J. Navas, INIA - National Institute for Agricultural and Food Research and Technology / Environment; A. Valdehita, INIA National Institute for Agricultural and Food Research and Technology / Department of Environment; J.A. Campillo, Instituto Español de Oceanografia / Centro Oceanográfico de Murcia; R. Moreno, Instituto Español de Oceanografia / Marine Contamination and Biological Effects; V. León, Instituto Español de Oceanografia / Centro Oceanográfico de Murcia

The Mar Menor (Murcia, SE Spain) is the biggest hypersaline coastal lagoon in the Mediterranean Sea, impacted by intensive agricultural activities, urban growth, massive tourism and historical metal pollution. In this study, we investigated the presence of steroid compounds and Aryl hydrocarbon receptor inducers in surface sediments from the lagoon using *in vitro* bioassays. Fifteen sediment samples from Mar Menor were tested for (anti)estrogenic, (anti)androgenic and EROD activity using the HER-Luc, AR-EcoScreen™ and fibroblast like RTG-2 cell lines, respectively. Organic extracts were prepared from total sediments using methanol (for hormonal, anti-hormonal and EROD measurements) and hexane:acetone (for EROD measurements). Overall, higher *in vitro* activity was detected in sediment extracts from depositional areas of the Lagoon (central and southern basins) and near main marinas. All but two sediment extracts induced EROD activity (maximum value 0.97 ng Eq β-Naphtoflavone/mg sed). Anti-estrogenic activity was also detected in eleven samples, of which five of them were able to block up to 80% of the response caused by EC50 of 17ß-estradiol. Anti-androgenic activity was found in six sediment extracts, of which all but one were able to decrease the effect caused by EC50 of dihydrotestosterone below 80%. None of the sediments extracts induced agonistic estrogenic or androgenic activity. Spatial patterns of *in-vitro* responses obtained in this study were compared with those of *in vivo* responses of sea-urchin pre-embryos exposed to sediment elutriates and with sedimentary organic contaminant concentrations (polycyclic aromatic hydrocarbons, polychlorinated biphenyls, surfactants, pesticides and pharmaceuticals) available from the same sampling cruise and stations. Certain dissimilarities between spatial distribution of chemical concentrations, *in vivo* and *in vitro* responses were observed. Further extensive chemical analysis for contaminant identification is underway to improve the interpretation of our findings. **Acknowledgement** - This work has been supported by Seneca Foundation (Region of Murcia, Spain) through 'BIOMARO' project (15398/PI/10) and by IMPACTA project.

MO191

Analysis of Polycyclic Aromatic Hydrocarbons (PAHs) in Lebanese surficial marine sediments

R. Manneh, University of Balamand / Department of Chemical Engineering; C. Abi Ghanem, G. Khalaf, E. Najjar, National Council for Scientific Research Lebanon / National Center for Marine Sciences; B. El Khoury, University of Balamand / Department of Chemistry; A. Iaaly, University of Balamand / Department of Mechanical Engineering; H. El Zakhem, University of Balamand / Department of Chemical Engineering

Organic contaminants are introduced to the marine environment through coastal oil refineries, shipping activities and accidental spills. The organic contaminants most commonly found in marine sediments are: Polychlorinated Biphenyls (PCBs), Organochlorine Pesticides (OCPs) and Polycyclic Aromatic Hydrocarbons (PAHs). The characterization of PAHs in Lebanese marine sediments is still a new field. The objectives of this research are to i) identify and characterize the concentration of PAHs in the sediments of Tripoli, Jounieh, Dora, and Tyre regions in Lebanon and ii) determine the possible sources of PAHs. Pre-sampling, sediment sampling, lyophilization, Soxhlet extraction, rotary evaporation and gas chromatography were performed. The total PAHs concentrations ranged from 2.49 to 731.93 μg/kg dry weight, with the lowest PAHs concentrations found in Tyre and the highest in Dora and Jounieh. The PAHs were mostly from pyrogenic sources.

Natural toxins: an on-growing challenge for environmental research, monitoring and management (P)

MO192

Harmful algal bloom smart device application: using image analysis and machine learning techniques for early classification of harmful algal blooms

M. Waters, Northern Kentucky University / Mathematics Statistics; M. Kannan, Northern Kentucky University / Biological Physical Sciences; J.M. Lazorchak, J. Allen, U.S. EPA / Office of Research and Development

The Ecological Stewardship Institute at Northern Kentucky University and the U.S. Environmental Protection Agency are collaborating to optimize a harmful algal bloom detection algorithm that estimates the presence and count of cyanobacteria in freshwater systems by image analysis. Green and blue-green algae exhibit different Hue-Saturation-Value color histograms in digital photographs. These differences are exploited by machine learning techniques to train a smart device (cellular phone, tablet, or similar) to detect the presence and amount of cyanobacteria in a small surface portion of a freshwater system. The Harmful Algal Bloom Classification Application (HAB APP) has been field tested and verified to classify both green and blue-green algae. Specifically, the APP has been tested on several small streams and ponds, correctly classifying green algal blooms and has been tested on the Ohio River, correctly classifying blue-green algae in the recent 636-mile long cyanobacteria bloom. The application is planned to be tested and optimized in Lake Harsha, a 22,000-acre reservoir which supplies six million gallons per day of drinking water to the Ohio county in which it lies and is a source of many recreational activities, including swimming, boating, and fishing. The application will be used on images taken from a freshwater intake facility. The presence and amount (or lack thereof) will be verified by other detection instruments and *in vitro* by agency scientists and hysteresis techniques will be used to monitor the presence and amount of cyanobacteria on a periodic (*e.g.* daily, seasonally) basis.

MO193

Global metabolomic characterizations of Microcystis spp. highlights clonal diversity in natural bloom-forming populations and expands metabolite structural diversity

S. Le Manach, UMR Molécules de communication et adaptation des microorganismes; C. Duval, MNHN / UMR Molécules de communication et adaptation des microorganismes; A. Marie, MNHN; M. Edery, MNHN / UMR Molécules de communication et adaptation des microorganismes; C. Bernard, S. Zirah, MNHN; B. Marie, MNHN / UMR Molécules de communication et adaptation des microorganismes

Cyanobacteria are photosynthetic prokaryotes that are able to synthetize a wild rang of secondary metabolites, with noticeable bioactivity (comprising toxicity) according to the ribosomal and non-ribosomal processes involving numerous NRPS/PKS clusters (Shih et al., 2013). *Microcystis* represents one of the most common cyanobacteria taxa constituting the intensive blooms that arise nowadays in freshwater ecosystems worldwide. These microorganisms produce numerous cyanotoxins (toxic secondary metabolites), which are potentially harmful to Human health and aquatic organisms. With the aim of contributing to better understand the variations in cyanotoxins production, such as microcystins (MC), between clones of the same cyanobacterial blooms, we investigate in the present study the diversity of several *Microcystis* strains isolated from different freshwater bloom-forming populations from various geographical area. Twenty five strains of *Microcystis* from the Paris' Muséum Collection of cyanobacteria (PMC) were compared by an integrated approach combining genotyping and metabolites chemotyping. These characterizations comprise analyses on morphology, Internal Transcript Spacer (ITS), microcystin synthesis gene, and global secondary metabolite contents. Complementary metabolomics shotgun analyses by MALDI-TOF and ESI-qTOF/TOF mass spectrometry reveal clear discriminant metabolic profiles between strains collected from identical or different localities. A global cluster analysis indicates that microcystin synthesis gene presence explains more of the metabolite diversity distribution, than the species or the sample localities do. A global network generated from MS/MS fractionation patterns of the various metabolite detected in all 25 strains performed with GNPS tool indicates that these *Microcystis spp.'* strains produce a wide set of chemically diverse metabolites, comprising only few microcystins, but many aeruginosins and microginins, together with a large set of unknown molecules that still remain to be investigated and characterized at their structure as well as at their potential bioactivity/toxicity levels. Shih et al. (2013) *Proc. Natl. Acad. Sci. U.S.A.* 110:1053-8

MO194

Cyanobacterial water blooms dominated by species from different orders produce teratogenic retinoid-like compounds into surface waters

L. Sehnal; T. Prochazkova, Research Centre for Toxic Compounds in the Environment, Faculty of Science, Masaryk University / Research centre for toxic compounds in the environment; O. Lepšová, Faculty of Science, University of South Bohemia; M. Smutna, Masaryk University / RECETOX; K. Hilscherova, Masaryk University, Faculty of Science, RECETOX / RECETOX

It is well known that cyanobacteria produce a diverse spectrum of compounds, some of which can cause adverse effects and pose risk to both aquatic organisms and human. Our study characterizes the presence of retinoid-like compounds in field cyanobacterial water blooms and their production to the surrounding waters. These compounds are important for a lot of physiological processes in living organisms, but also belong to the most potent compounds causing teratogenity. The first part of research focused on testing various processing approaches using solid phase extraction (SPE) for the most effective recovery of retinoid-like mixtures and their concentration from surface waters samples. Extracts of model

cyanobacterial biomasses of common species as well as artificial mixtures of several retinoid-like compounds were used during the optimization process. The total retinoid-like activity was determined by *in vitro* assessment using transgenic cell line P19/A15, the concentration of individual compounds was analysed by LC-MS-MS. Ten distinct procedures were tested for optimization of the sample processing with laboratory samples and model mixtures. Three procedures were selected for processing of samples from field study conducted during summer 2015. Samples of biomass and surrounding water were collected from seventeen independent reservoirs or ponds with massive water bloom distributed throughout the Czech Republic. The detailed taxonomical analyses characterized the composition of the water bloom and revealed dominance of different species. Two of the selected procedures were efficient in concentrating the retinoid-like compounds from field water samples showing comparable results. The water samples from five study sites have shown retinoid-like activity over 20 ng/L equivalent concentration of standard retinoid all-trans retinoic acid (ATRA). The greatest detected retinoid-like activities in water affected by cyanobacterial water blooms reached several hundreds ng ATRA equivalent/L. Study shows that phytoplankton blooms of different composition can produce retinoid-like compounds to aquatic environment. Their production could directly affect the present organisms, especially sensitive early developmental stages, namely in case of massive water bloom development, which is a common problem in many surface waters. The work was supported by the Czech Science Foundation grant No. 14-29370P.

MO195

Influence of natural compounds produced by phytoplankton on the effects of anthropogenic estrogens commonly co-occurring in surface waters

J. Javurek, Research Centre for Toxic Compounds in the Environment (RECETOX) / RECETOX Research Centre for Toxic Compounds in the Environment; L. Sehnal, B. Jarosova, Masaryk University / RECETOX Research Centre for Toxic Compounds in the Environment; E. Sychrova, Masaryk University / Research centre for toxic compounds in the environment RECETOX; T. Prochazkova, Research Centre for Toxic Compounds in the Environment, Faculty of Science, Masaryk University / Research centre for toxic compounds in the environment; K. Hilscherova, Masaryk University, Faculty of Science, RECETOX / RECETOX

Adverse endocrine disruptive effects of (xeno)estrogens on aquatic biota have been known for decades. Some of the most potent estrogens like steroidal hormones estrone, estradiol, estriol and ethinylestradiol occur in surface waters world-wide. In addition, other less known chemicals, such as phytoestrogens, can contribute to estrogenic activity. Moreover, overall activity results from complex of both agonists and antagonists functioning of chemicals present in environmental mixtures. Apart from man-made pollutants, wide spectra of chemicals in aquatic environments are produced by harmful algal blooms, including some known phytoestrogens. This study combines results from field sampling with laboratory investigations to evaluate the role of phytoplankton metabolites in estrogenic activity of environmentally relevant mixtures in co-exposure with anthropogenic pollutants. Our research has shown estrogenic activities in biomasses of phytoplankton water blooms of various taxonomic composition from some freshwater reservoirs, where also several anthropogenic estrogens have been detected. The potential influence of the phytoplankton produced compounds on the effects of anthropogenic pollutants has been investigated in detail. The interference with estrogenic receptor has been characterized for extracts of broad spectra of cyanobacterial and algal species from different orders including several widespread species frequently dominating water blooms. The extracts were tested alone and in co-exposure with relevant anthropogenic pollutants that were shown to commonly co-occur with the water blooms. The study represents an example of combination of chemical and biological approaches to investigate less known but widespread sources of estrogens and realistic scenario of mutual interactions of anthropogenic and natural compounds acting in mixtures. The study was supported by the Czech Science Foundation within the project P503/12/0553 and EU FP7 project SOLUTIONS (No. 603437).

MO196

Genotoxicity of complex mixtures of compounds extracted from different strains of cyanobacteria

M. Bittner, M. Smutna, Masaryk University / RECETOX; K. Hilscherova, Masaryk University, Faculty of Science, RECETOX / RECETOX; B. Zegura, National Institute of Biology / Department of Genetic Toxicology and Cancer Biology

The occurrence of cyanobacterial blooms has increased significantly in many regions of the world in the last century due to water eutrophication. These blooms are hazardous to humans, animals, and plants due to the production of cyanotoxins, which can be classified in five different groups: hepatotoxins, neurotoxins, cytotoxins, dermatotoxins, and irritant toxins (lipopolysaccharides). There is evidence that certain cyanobacterial toxins, such as microcystins, nodularins and cylindrospermopsins are genotoxic and carcinogenic. However, the mechanisms of their potential carcinogenicity are not well understood. In our research, we focused on genotoxic effects of complex biomass extracts from laboratory cultured cyanobacteria species. The greatest tested concentration of samples was 2 mg_{DM} /mL (DM – dry mass). However, some of the extracts were cytotoxic at this level, thus genotoxic evaluation was done only for non-cytotoxic levels. The genotoxic potentials of cyanobacterial extracts were evaluated using Single cell gel electrophoresis method (Comet assay) and Cytokinesis-block micronucleus cytome assay (Micronucleus test) , both by using human hepatoma HepG2 cell line. Comet assay reveals single and double strand breaks, and other abnormalities on DNA associated with incomplete excision repair, whereas Micronucleus test is a method for the evaluation of genomic instability. Using Comet assay, positive effects were shown for four cyanobacterial extracts: *Cylindrospermopsis raciborski* at levels 0.2 – 2 mg_{DM}/mL, *Aphanizomenon gracile* at levels 1 – 2 mg_{DM}/mL, *Limnothrix redekei* at level 1 mg_{DM}/mL, and *Microcystis ichtyoblabe* at level 0.2 mg_{DM}/mL. Using Micronucleus test, no positive effects were observed for any of tested cyanobacterial samples (tested at level of 0.2 mg_{DM}/mL, which was non cytotoxic level for all tested samples); positive efects were exerted only by control samples (cylindrospermopsin at level 0.5 μg/mL, Benzo[a]Pyrene at level 2.5 μg/mL, and Etoposide at level 1 μg/mL). Results of our research confirmed hypothesis that complex samples of some cyanobacterial species can exert genotoxic effects, similarly to effects of certain pure cyanotoxins. *This research was supported by the grant Cyanocost COST-STSM-ES1105-24073 and the Czech Science Foundation grant No. GACR P503/12/0553.*

Toxicity of cyanotoxins to human liver stem cells: effects on 2D and 3D cultures

A. Basu, RECETOX, Faculty of Science, Masaryk University / Ecotoxicology; A. Dydowiczova, Masaryk University Faculty of Science RECETOX / RECETOX; S. Váňová, Masaryk University, RECETOX / RECETOX; I. Sovadinova, Masaryk University; P. Babica, L. Blaha, Masaryk University, Faculty of Science / Research centre for toxic compounds in the environment RECETOX

Occurrence of cyanobacterial blooms poses a serious threat to the environment and human health due to the production of cyanobacterial toxic metabolites. Microcystins (MCs) and cylindrospermopsin (CYN) are considered to be the most hazardous cyanobacterial secondary metabolites; since they are not only associated with acute toxicity but they can induce also long term adverse effects at chronic exposures. In our study, we investigated hepatotoxic and hepatocarcinogenic effects of cyanotoxins using novel *in vitro* model of HL1hT1 cell line, which represent hTERT-immortalized adult human liver stem cells. HL1hT1 cells are characterized by expression of stem and liver oval cell markers, high proliferation potential, ability of anchorage-independent growth, and lack of gap junctional intercellular communication (GJIC). Micromolar concentrations of CYN induced strong cytotoxic effects in HL1ht1 grown in traditional monolayer (2D) cultures primarily affecting respiration (Alamar Blue assay) and cell energetic metabolism (Neutral Red uptake) rather than membrane integrity (CFDAAM assay). On the other hand, growth and viability of HL1hT1 cells were not affected by MC-LR up to concentration 10 micromol/L. In 3D spheroid culture, HL1hT1 cells became more sensitive to cyanotoxin treatment, where both MC-LR and CYN inhibited formation, growth and viability of spheroids (Alamar Blue) even at concentrations at low as 0.1 micromol/L. The observed increase in the sensitivity of spheroid cultures indicate the ability of liver stem cells to differentiate in 3D microenvironment and to better recapitulate physiological liver-specific gene expression patterns and functions, such as expression of proteins involved in cyanotoxin cellular uptake or bioactivation. This study demonstrates that 3D cultures of adult human liver stem cells HL1hT1 represent a perspective in vitro model which allows studying hepatotoxic, tumor promoting and carcinogenic effects of toxicants and understanding thus the role of stem cells in the development of chronic diseases and toxicities. Support: Project GA15-12408S funded by the Grant Agency of the Czech Republic.

MO198

Uptake and biotransformation of cyanobacterial toxins in cultures of liver progenitor and stem cells

L. Jasa, RECETOX, Faculty of Science, Masaryk University / RECETOX; H. Klimova, Masaryk University, RECETOX / RECETOX; A. Basu, RECETOX, Faculty of Science, Masaryk University / Ecotoxicology; S. Váňová, J. Raska, Masaryk University, RECETOX / RECETOX; L. Blaha, Masaryk University, Faculty of Science / Research centre for toxic compounds in the environment RECETOX; P. Babica, Masaryk University, RECETOX / RECETOX

Cyanobacterial toxins (cyanotoxins) represent important group of aquatic contaminants. Microcystins and cylindrospermopsin are recognized as the most hazardous cyanoxins with respect to their potential for both acute and chronic effects on human or wildlife health. These substances cause primarily hepatotoxic or hepato-carcinogenic effects in mammals, however they might cause negative effects also to other tissue or organ cells, such as kidneys, gastrointestinal tract, neural or immune systems. Organ- and tissue-specific effects of cyanotoxins are most likely governed by differential expression of genes responsible for cyanotoxin cell uptake, bioactivation/biotransformation and elimination, which might dramatically differ among various cell types. In this study, we investigated *in vitro* uptake and biotransformation of cyanotoxins microcystin-LR and cylindrospermopsin in experiments with tissue cultures of rat and human liver progenitor or stem cell lines, namely rat liver epithelial cell line WB-F344 which exhibit characteristics of multipotent liver progenitor cells, and hTERT immortalized adult human liver stem cell line HL1hT1. Sensitive and reliable LC-MS/MS method was used to monitor concentrations of parental cyanotoxins as well as their biotransformation products in the cell culture medium collected from monolayer cultures of undifferentiated and differentiated liver progenitor/stem cells, and also from 3D spheroid cultures of WB-F344 and HL1hT1 cells. Western blot analysis using specific antibodies directed against microcystin-LR was used to detect microcystin-protein adducts in the cells. Using our approach, we were able to characterize ability of each cell line to intake and metabolize microcystin-LR and cylindrospermopsin, to characterize effects of cell culture conditions on the kinetics of toxin uptake and transformation, and to correlate these differences with the changes in expression and activity of proteins responsible for the cell uptake of microcystin-LR (organic anion-transporting polypeptides) and biotransformation of cylindrospermopsin (CYP450). MO199

In vitro effects of cyanotoxins on normal and transformed rat liver epithelial cell lines

L. Ctverackova, RECETOX; A. Basu, A. Dydowiczvá, R. Škovroňová, P. Babica, Masaryk University / RECETOX   Research centre for toxic compounds in the environment

Massive proliferations of toxic cyanobacteria (blue-green algae) in aquatic ecosystems deteriorate water quality of freshwaters and have become global environmental problem nowadays. Toxic compounds produced by cyanobacteria pose hazards to wildlife or human health when present in water bodies used as drinking water source or for recreational purposes. Cyanobacterial toxins (cyanotoxins) are divided in chemically and toxicologically different groups, whereas microcystins and cylindrospermopsin are currently considered to be the most hazardous cyanotoxins, since they have been associated not only with acute toxicity, but also shown to induce long term adverse effects at chronic exposures, including liver tumor promoting and/or carcinogenic effects. In this study, we used *in vitro* models based on rat liver epithelial cell line WB-F344, which express markers of liver progenitor-/-oval cells. WB-F344 cells are not capable of anchorage-indepedent growth (AIG), maintain functional gap junctional intercellular communication (GJIC), and they are sensitive to contact inhibition of growth. These non-tumorigenic cells can be neoplastically transformed by ras oncogene. Transformed WB-ras cells are characterized by increase of AIG, downregulated GJIC, reduced contact inhibition of growth, and *in vivo* tumorigenicity. Normal (WB-neo) and ras-transformed (WB-ras) rat liver epithelial cells, were used to study effects of cyanotoxins microcystin-LR and cylindrospermopsin on cell growth and viability in traditional 2D monolayer cultures as well as in 3D spheroid cultures. Antiproliferative/cytotoxic activity of cyanotoxins was strongly dependent on the cell type (WB-neo/WB-ras) as well as on the type of cell culture system (2D/3D). The results indicate that exposure to cyanobacterial toxins provides selective growth advantage to undifferentiated and/or transformed cells over normal differentiated cells. These selective effects occur most probably because of different gene expression patterns and biochemical characteristics between these cell types, possibly including genes involved in toxin uptake or bioactivation. Cell type-specific effects of cyanotoxins might represent an important mechanism leading to disruption of liver tissue homeostasis, and thus contribute to their tumor promoting and carcinogenic effects. Support: Czech Science Foundation Project No. GA15-12408S.

Innate immunity response to an important freshwater polluting cyanobacterial toxin

Z. Moosova, Masaryk University, Faculty of Science / Research centre for toxic compounds in the environment RECETOX; O. Adamovsky, Masaryk University, Faculty of Science, RECETOX / Research centre for toxic compounds in the environment RECETOX; M. Pekarova, Academy of sciences of Czech Republic / Institute of biophysics; A. Basu, P. Babica, Masaryk University, Faculty of Science / Research centre for toxic compounds in the environment RECETOX; L. Svihalkova Sindlerova, L. Kubala, Academy of sciences of Czech Republic / Institute of biophysics; L. Blaha, Masaryk University, Faculty of Science / Research centre for toxic compounds in the environment RECETOX

Cyanobacteria are ubiquitous photosynthesizing gram-negative bacteria associated with toxic water bloom in freshwater lakes, frequently serving as source of drinking water. Cyanobacterial production of a wide range of hepatotoxins, neurotoxins and dermatotoxins affects water quality, which is rising environmental and health concern worldwide. One of the most common cyanobacterial toxins are microcystins (MCs). Due to their stability in the environment and high risk to human health, the WHO has established a provisional guideline of 1μg/L for microcystin-LR (MC-LR) in drinking water. Whereas, the hepatotoxic potential of MCs was studied extensively, there is general lack of studies focused on the effects of cyanobacterial metabolites on immunity. The aim of our study was to determine the effects of MC-LR on physiological functions of macrophages (RAW 264.7), which represent one of the key effector immune cells. In our study, we used the concentrations of MC-LR (1 - 1000 nM), which were reported in human blood and thus are considered as relevant. Importantly, we have shown that even nanomolar concentrations of MC-LR significantly stimulated the production of pro-inflammatory cytokines, which could negatively affect human health. Interestingly, we found that the MC-LR-induced changes were not attributed to the inhibition of protein phosphatases activity, due to the lack of microcystin trans-membrane transporters. Considering all pieces of evidence gathered in the present study, we hypothesize that MC-LR is able to directly interfere with macrophage surface receptors that trigger the signaling pathways and thereby alter immune response. These results suggest that MC-LR have significant immunomodulatory activities even in very low and environmentally relevant concentrations. The research was supported by the projects of the Czech Ministry of Education LO1214 and LM2011028, and by the CYANOCOST action (EU COST ES1105). \n \n

MO201

Intracellular and extracellular retinoid-like activity of widespread cyanobacterial species

J. Priebojová, Masaryk University, Faculty of Science, RECETOX; M. Smutna, Masaryk University / RECETOX; E. Sychrova, J. Dansova, Masaryk University / Research centre for toxic compounds in the environment RECETOX; K. Hilscherova, Masaryk University, Faculty of Science, RECETOX / RECETOX

Cyanobacteria are common and potentially harmful inhabitants of freshwater worldwide. They are producers of various types of bioactive compounds, which are toxic and they may cause animal death, embryotoxicity, teratogenicity and adversely affect human health. Recent studies indicate that some phytoplankton species can produce retinoid-like compounds that could contribute to some of these effects. Retinoids comprise a family of polyisoprenoid lipids which include vitamin A and its natural and synthetic analogues. These substances act by binding to retinoic acid receptors (RAR), and regulate proliferation, differentiation, apoptosis, cytokine production, gut mucosal immunity and malignant transformation of cells. The aim of our work was to evaluate the variability in production of retinoid-like compounds, which could be released into the environment, by selected widespread cyanobacterial species. We tested *in vitro* potential of extracts and exudates from laboratory-cultured species to induce responses mediated through retinoid acid receptor (RAR) using transgenic murine embryonic carcinoma cell line, which contains reporter luciferase gene under the control of retinoic acid-responsive element. The detailed investigations focused on commonly occurring cyanobacterial species with tendency to form massive water blooms, one coccal (*Microcystis aeruginosa*) and four filamentous cyanobacteria (*Aphanizomenon gracile, Limnothrix redekeii, Cylindrospermopsis raciborskii* and *Planktothrix agardhii*). We analysed 18 extracts and exudates of the five different cyanobacteria. We found activation of retinoid receptor after exposure to intracellular samples from all studied cyanobacterial species. The cyanobacterial exudates of all species except of *P.agardhii* also contained retinoid-like activity reaching up to over 6 μg/l in case of one cultivation of *L.redekeii*. We have recalculated total produced retinoid-like activity using extract and exudate data for each tested cyanobacterial species. The total retinoid-like activity of the five selected species ranged from 0.1 to several μg ATRA/g dry weight. The production of retinoid-like compounds was recalculated to biomass dry weight as well as to cell density. This enables to estimate the production in environmental biomasses characterized by cell density and thus assessment of risks of the produced retinoid-like compounds. The research was supported by the Czech Science Foundation grant No. 14-29370P.

CYANOCOST: an EU COST Action on Cyanobacterial Bloom and Cyanotoxin Risk Management

L. Blaha, Masaryk University, Faculty of Science / Research centre for toxic compounds in the environment RECETOX; G. Codd, University of Stirling; A. Hiskia, NCSR Democritos; T. Kaloudis, EYDAP S.A.; J. Meriluoto, Åbo Akademi; A. Quesada, Autonomous University of Madrid; Z. Svircev, University of Novi Sad; P. Visser, University of Amsterdam

CYANOCOST project includes over 100 active participants from 35 European and neighbouring countries. This EU COST ES1105 Action (www.cyanocost.com) runs from 2012 to 2016 and is focused on the assessment and mitigation of problems presented throughout Europe and beyond by cyanobacteria and cyanotoxins in water resources. Working groups of the action include: (i) collecting information on cyanobacteria and cyanotoxins in European waters and identifying appropriate methods for monitoring and analysis; (ii) assessing data on fate, environmental and health impacts as well as on the economy and wider society; (iii) identifying measures for the reduction of cyanobacterial bloom development by in-lake and catchment methods, and for control of drinking water quality; and (iv) dissemination to end-users and stakeholders in the water resources and environmental sectors, plus the general public. This EU Action aims to disseminate best practices for the monitoring and analysis of cyanobacterial blooms and cyanotoxins, which is supported by four major outcomes of the action (handbooks and special journal issues) that focus on (1) Cyanobacterial monitoring and cyanotoxin analysis; (2) Molecular methods;

(3) Prevention, control and mitigation of cyanobacteria; (4) Drinking water treatment and cyanotoxins.

Behavioural and physiological responses of the oyster Crassostrea gigas exposed to three strains of Alexandrium minutum producing different toxin types
J. Castrec, LEMAR UMR 6539 CNRS / UMR CNRS UBO IRD Ifremer; P. Soudant, LEMAR UMR 6539 CNRS/UBO/IRD/Ifremer; L. Payton, D. Tran, EPOC University of Bordeaux; P. Miner, Ifremer, LEMAR UMR 6539 CNRS/UBO/IRD/Ifremer; C. Lambert, N. Le Goïc, LEMAR UMR 6539 CNRS/UBO/IRD/Ifremer; A. Huvet, V. Quillien, Ifremer, LEMAR UMR 6539 CNRS/UBO/IRD/Ifremer; F. Boullot; H. Hégaret, LEMAR UMR 6539 CNRS/UBO/IRD/Ifremer / UMR CNRS Ifremer IRD UBO; C. Fabioux, LEMAR UMR 6539 CNRS/UBO/IRD/Ifremer
Blooms of the dinoflagellate *Alexandrium* spp, producers of Paralytic Shellfish Toxins (PST), are regularly detected on the French coastline. PST accumulate into harvested species, such as the Pacific oyster *Crassostrea gigas*, and can cause strong disorders to consumers at high doses. The impacts of *Alexandrium minutum* on *C. gigas* have often been attributed to its production of PST; however some studies revealed that these algae can also produce extracellular substances, some of which have allelopathic or ichthyotoxic properties. These compounds are excreted in the environment thereby impacting phytoplankton, zooplankton but also marine invertebrates and fishes, without implicating any PST. The chemical identity of those extracellular compounds is still unknown. The aim of this work was to compare the effects of three strains of *A. minutum* producing either only PST, only none-PST extracellular compounds, or both PST and none-PST extracellular compounds, on the oyster *C. gigas*. Behavioural and physiological responses of oysters exposed during 4 days to these three strains of *A. minutum* were therefore compared in order to discriminate between the effects attributable to PST and those induced by extracellular compounds. Our results indicate that the three strains of *A. minutum* induced different behavioural and physiological responses of oysters probably depending on bioactive substances produced by each strain. The extracellular-compound-producing strain primarily modifies valve-activity behaviour of *C. gigas* and induces hemocyte mobilization in the gills whereas the PST-producing strain causes inflammatory responses in the digestive gland. These results suggest that extracellular compounds have a significant harmful effect on the gills, which is the first organ in contact with the extracellular substances released in the water by *A. minutum*. Conversely, the PST impact the digestive gland, where paralytic toxins are released and mainly accumulated, after degradation of algal cells during digestion process of bivalves. This study provides a better understanding of the toxicity of *A. minutum* on oyster, and also highlights the significant role of extracellular bioactive compounds in this toxicity and the need to characterize these substances. Keywords: *Alexandrium minutum*, PST, extracellular bioactive compounds, oyster.

MO204
First insights in the characterization of allelopathic and cytotoxic extracellular compounds from the toxic dinoflagellate Alexandrium minutum

Hégaret, LEMAR UMR 6539 CNRS/UBO/IRD/Ifremer / UMR CNRS Ifremer IRD UBO
Harmful Algal Blooms (HABs) result from the rapid increase and growth of toxic microalgae, predominantly dinoflagellates, in marine ecosystems. HABs are of major interest because of their effects upon fisheries and human health. Dinoflagellates from the genus *Alexandrium* have the potential to produce paralytic shellfish toxin (PST) and release unknown extra-cellular compounds (ETC) with cytotoxic, hemolytic, ichtyotoxic and allelopathic activity. These ETC have deleterious effects upon various organisms and specific cell types with poorly described effects. A recent study by our group on physiological responses of oysters exposed to different *A. minutum* strains has revealed that the strain releasing ETC had more deleterious effects than the strain producing PST. This highlights the importance of characterizing the ETC produced by *Alexandrium* spp. as well as their modes of biological action. The nature of these ETC remains a mystery, and the relevant literature is sparse and inconsistent. It is not clear if one or more compounds with different properties are involved in the observed deleterious effects. To begin characterizing the ETC produced by *A. minutum,* we first investigated possible deleterious effects of the compounds on three cell types: diatoms *Chaetoceros neogracile*; and bivalves hemocytes (*Crassostrea gigas* and *Merceneria merceneria*). To explore the chemical nature of putative ETC, we mitigated effects using enzymes assays with protease (trypsin) and a reactive oxygen species (ROS) scavenger (superoxide dismutase). Aqueous filtrate of *A. minutum* impacted the photosystem II activity in *C. neogracile*, as measured by pulse amplitude modulated fluorometry, and this deleterious effects was not mitigated by trypsin. This suggests that the lytic protein-like compounds, previously identified in the literature, might not be the same as those affecting the photosystem II. This highlights that two or more different compounds may be involved in allelopathy. The aqueous filtrate induced a decrease in phagocytosis and in mitochondrial membrane potential, as well as an increase in ROS production in bivalve hemocytes measured by flow cytometry. Superoxide dismutase partially mitigated the effects of the filtrate upon phagocytosis suggesting that ROS were involved in cytotoxicity. Further studies are needed to better characterize the compounds and understand if the allelopathic compounds are also responsible for the cytotoxic effects on bivalve hemocytes.

MO205
ALEXNEXT - Alexandrium sp. analysis by Next-Generation Sequencing
G. Giménez Papiol; M. Schuhmacher, Rovira i Virgili University / Chemical Engineering
Harmful algal blooms (HABs) are blooms of microalgae able to produce toxic compounds that are accumulated by shellfish and affect human health through its consumption. Monitoring programs are aimed at avoiding the ingestion of these toxins by forbidding the harvest of shellfish when a HAB outbreaks and/or toxin levels in shellfish flesh are over a legally regulated level. Research and monitoring of marine toxic microalgae tend to reduce the costs and time between the sampling and the results, in order to support decisions that affect human health, food safety and aquaculture and fisheries economy. Shellfish aquaculture is an important economic activity in some coastal areas of Cataloniaand Spain. There have been several closures of Catalan shellfish harvesting areas due to the presence of Paralytic Shellfish Poisoning (PSP) toxins in shellfish flesh since the beginning of the monitoring program in 2002; spirolides were confirmed in 2014. *Alexandrium* species are among the main producers of PSP toxins and spirolides. There are 6 *Alexandrium* species normally detected in Catalan coastal waters, 3 of which produce PSP toxins (*A. minutum*, *A. catenella* and *A. tamarense*), 1 is known to be toxic (*A. preuvianum*) and 2 are considered non toxic (*A. insuetum* and *A. margalefii*). Methods for microalgae identification (microscopy) and toxin detection (e.g. chemical and immunological) are often laborious and expensive. Recently, several genetic techniques have been developed for the study of microalgae diversity; among which, NGS, whose throughput exceeds by millions of times the Sanger sequencing, producing high amounts of data cheaply and spreading the use of genetic analysis to a wide spectrum of scientific disciplines. These characteristics make NGS especially attractive for environmental risk monitoring and public health management. The project ALEXNEXT – *Alexandrium* sp. analysis by Next-Generation Sequencing (TECSPR14-2-0012) is a proof of concept of the suitability of a NGS technique for identifying and quantifying marine microalgae. First, specific primers will be developed and tested on single-species *Alexandrium* samples. Tiered communities based on the DNA or the PCR products of the same *Alexandrium* samples will be made to investigate the limits of detection and the ability to quantify the content of each individual *Alexandrium* species DNA in the sample. Finally, the suitability of NGS will be assessed using selected samples collected from the Catalan coast.

MO206
Cytotoxicity to fish cell lines and endocrine effects of the mycotoxins beauvaricine, deoxynivalenol and ochratoxin-A
V. García Herranz, INIA - National Institute for Agricultural and Food Research and Technology; A. Valdehita, INIA National Institute for Agricultural and Food Research and Technology / Department of Environment; A. Valverde-de la Fuente, INIA National Institute for Agricultural and Food Research and Technology; J. Navas, M. Fernandez-Cruz, INIA - National Institute for Agricultural and Food Research and Technology / Environment
Mycotoxins are natural metabolites of fungal species. They can be especially abundant on grain, and therefore there is increasing concern about their effects for humans and livestock. They can also lead to environmental problems. For instance, they can reach water bodies by leakage or run-off from crop fields affecting fish. Cultured fish can also be exposed to mycotoxins by ingestion of contaminated feed containing grain as a protein source. The toxicity of mycotoxins is well recognized in mammals, but their effects on fish have hardly been investigated. Moreover, in the last years evidence that some of them may act as endocrine disruptors is increasing. The aim of this study was to determine the cytotoxic effects of three mycotoxins, beauvaricine (BEA), deoxynivalenol (DON) and ochratoxin-A (OTA) on two fish hepatoma cell lines (PLHC-1 and RTH-149) and to evaluate their endocrine activities at receptor level. Cytotoxicity was determined by the Alamar Blue, Neutral Red Uptake and CFDA-AM assays after 24 h of exposure to each mycotoxin. For the assessment of androgenic, estrogenic and thyroidal (anti)activities three cell lines permanently transfected with luciferase as reporter gene under the control of hormone receptors were used: AR-EcoScreen cell line with the human androgen receptor (hAR), HER-LUC with the sea bass estrogen receptor (sbER) and PC-DR-Luc cell line with the avian thyroid receptor α (THRα). Results obtained in this work showed that both fish cell lines were very sensitive to the three mycotoxins tested. DON was the most toxic followed by BEA and OTA. None of the three mycotoxins tested activated any of the three types of receptors under study. However, all of them showed anti-hormonal activity, thus being able to decrease the response caused by the effective concentration 50 (EC_{50}) of the corresponding hormone: dihydrotestosterone (DHT), 17β-estradiol (E2) or Triiodotyronine (T3). OTA

(0.02μM) showed antiestrogenic activity, provoking a reduction of the luminiscence induced by E2 EC_{50} (0.07μM). BEA presented anti-androgenic activity and DON and OTA anti-thyroidal activity, at concentrations 1000 times higher than this of the EC_{50} of DHT (0.09 nM) and of T3 (0.09 nM). The data obtained in this work showed a high sensitivity of fish cell lines to the three mycotoxins tested and evidenced that these mycotoxins are endocrine disruptors at receptor level. Surfactants from natural products Itaconic and Fumaric Acids: their ecotoxicity and potential for green chemistry

M.B. Gösser, University of Bologna / The School of Life Sciences; E. Tagliavini, Università di Bologna / Dipartimento di Chimica G Ciamician Alma Mater Studiorum; C. Samorì, Università di Bologna / Dipartimento di Chimica Giacomo Ciamician; P. Galletti, Università di Bologna / Dipartimento di Chimica G Ciamician; Z. Gajda-Meissner, T.F. Fernandes, Heriot-Watt University / School of Life Sciences

Interest in surfactants obtained from renewable sources has increased considerably due to their broad spectrum of industrial and everyday applications, the urgent need of decreasing the environmental impact of various chemical products and the general requirement of a more sustainable chemistry that no longer relies on fossil hydrocarbons. One interesting group of surfactants that can be synthesized in a sustainable manner includes products that can be obtained from fatty amines and itaconic and fumaric acids. Itaconic acid can be obtained from the fungal fermentation of waste biomass and is considered to be non-hazardous and biodegradable. Fumaric acid is a biogenic compound, considered to be in general non-hazardous. A series of different compounds have already been synthesized from these acids and have been evaluated focussing on their physicochemical properties and rheological behaviours. In this work a toxicological characterization of the surfactants was conducted in order to evaluate the safety profile of these products. Acute toxicity tests of 6 different surfactants, all of them having a C12 alkyl chain and most of them a 2-pyrrolidone ring, using *Daphnia magna* were carried out as a first step. Following the OECD guideline 202, young daphnids, aged less than 24 hours at the start of the test, were exposed to the test substance at a range of 7 concentrations for a period of 48 hours. Immobilization was recorded at 24 hours and 48 hours and compared with control values. Results obtained indicated EC_{50} (48 hrs) values ranging from 0.5 mg/L to close to 100 mg/L. The most toxic chemicals are now the focus of chemical modifications which aim either to lower the toxicity observed, or to increase it in view of possible uses as bacterial biocides.

MO208

Comparative toxicity of Quillaja saponins extracts and fractions

X. Jiang; A.M. Hansen, B.W. Strobel, H.C. Hansen, Univeristy of Copenhagen / Plant and Environmental Sciences; N. Cedergreen, University of Copenhagen / Plant and Environmental Sciences

Saponins are natural surfactants, found abundantly in various plant species. Quillaja saponins (extracted from *Quillaja saponaria*) have been approved for use as a type of biofungicide. The extract contains around 70 structurally distinct saponin fractions. Among all fractions, QS-18 is the dominant and most toxic one. Another fraction, the QS-21 fraction, is widely used as an adjuvant. The Quillaja extract contains around 13.5% of QS-18 and 3.7% of QS-21. However, most research so far has been done on the entire plant extract containing all saponins as well as other bioactive compounds. Hence, it is not specifically known where the bioactivity comes from: the saponins or non-saponin content. In addition, as only few of the saponin fractions can be analytically detected, the half-lives in different environmental compartments are rarely known. In this study, the QS-18 and QS-21 fractions were isolated by preparative HPLC. The two isolated fractions will be used in both toxicity and degradation studies. Their toxicities will be compared with the toxicities of the commercially available extracts,Quillaja Saponin S7900® (>10% saponin content) and Quil-A® (>95% saponin content), with 48-h *Daphnia magna* and 30-min *Vibrio fischeri* tests. The relative concentration of the different saponin fractions will be calculated by an internal standard (α-Hederin) using LC/MS. Preliminary results show EC_{50} of Quillaja Saponin S7900® and Quil-A® extracts towards *Daphnia magna* equal to 32.4 ± 1.0 and 19.3 ± 0.6 mg/L, respectively. When the relative concentrations of the different saponin fractions have been determined, the relative contribution of the total and the two fractions can be determined using the assumption of concentration addition. Knowledge of the toxicity of the different saponin fractions together with knowledge of their degradation under different conditions, will contribute considerably to environmental risk assessment of saponin applications.

MO209

Exposure and risks of aquatic organisms to genetically modified corn pollen

M.H. Wagelmans, Bioclear; E. Dijkhuis, FLORON

In this study the potential exposure of aquatic organisms to Bt-proteins in Corn pollen has been examined. The objective of this study was to gain insight into the potential exposure of aquatic organisms to Bt-proteins in Corn pollen and estimating the possible effects of this exposure in order to assess whether or not the aquatic ecosystem needs to be considered in the admission of transgenic Bt-corn events in the Netherlands. This research was performed commisioned by COGEM (The Netherlands Commission on Genetic Modification). The research was carried out in phases. The first phase was a literature review to gain insight in the exposure routes and dose-effect relationships. The second phase was a field study to determine pollen deposition and dispersion in surface water. For this purpose, samples were taken in waterways bordering plots with Corn. A total of nine sub locations have been sampled across three areas in the Netherlands. In addition a column test was carried out in order to determine how long pollen of Corn are residing in the water column. In phase 3 the results of the literature study and field study were combined and potential effects on aquatic organisms to Bt-proteins in Corn pollen were estimated. Also, just after the harvest, a visual inspection of the waterways was conducted to verify the assumption that crop residues of Corn in the Dutch situation do not end up in waterways. We have concluded that: It is likely that aquatic organisms are exposed to plant material and pollen of Corn if cultivation takes place adjacent to surface water. In case of cultivation of Bt-Corn potential risks of Bt-proteins for organisms in the aquatic environment are assessed as very low (based on the measurements of pollen deposition, numbers of pollen in surface water and dose-effect relations described in literature. At this moment, based on current knowledge, the aquatic ecosystem does not need to be considered at admission of new GM event of Corn.

The risk mitigation of E. coli O157 in agricultural environment

n. turgut; O. Kaya, Adnan Menderes University; . Kńrkhan, Adnan Menderes University / ad; U. Parфn, Adnan Menderes University

Escherichia coli O157:H7 causes several outbreaks as foodborne diseases by consuming leafy vegetables as lettuce and this pathogen has emerged as very important public health issues because of tthe gastrointestinal illness and long-term, chronic sequelae from an infectionтin many countries including Turkey. Many studies have shown that a definitive relationship between eating of leafy vegetables and human diseases. E. coli originates mainly from animal sources and then transfer to field crops and retail chains. The fate of the species in finishing products that are sold in the local and chain markets was monitored regulary two years long. The samples were inoculated to SMAC Agar and The colonies that grew on CT-SMAC agar and sorbitol negative ones were inoculated to Fluorocult_*E. coli*_O157:H7 agar. The susceptible colonies were examined with pouring 1 ml of Kovacs reagent for confirmation. Latex agglutination tests were made for confirmation. The prevalance of E. coli from lettuce was lower in local markets compared to chain markets. The possible contamination way of lettuce is during irrigation water which pumped from rivers that are contaminated from sewages. the leaves of lettuce become contaminated from manure that are used as fertiliser without waiting enough to decrease the contamination. The next step of this study will be how to prevent the contamination from this source and develop a new methodology for this purposes.

Advances in exposure modelling: bridging the gap between research and application (P)

MO211

How to account for the variability in chemical emissions from consumer products?

M. Douziech, Radboud University Nijmegen / Institute for Water and Wetland Research; A. Franco, Unilever / Safety and Environmental Assurance Centre SEAC; J. Hendriks, Radboud University Nijmegen / Department of Environmental Sciences; M. Huijbregts, Radboud University Nijmegen / Department of Environmental Science; H. King, Unilever RD Colworth; R. Oldenkamp, Radboud University Nijmegen / Department of Environmental Science; R. Van Zelm, Radboud University / Department of Environmental Science

To quantify the environmental risk of the increasing use of personal care products, accurate emission estimates of their components are required. In order to be reliable, these estimates need to consider the variability bound with the use of those products. Variability is induced by economic, demographic and social factors as well as by differences in consumer behaviour. Accounting for this variability is important to identify chemical emission hotspots. Recent (top-down) tonnage approaches estimate chemical emissions through disaggregation at smaller spatial resolution of products sales data using information about population density and GDP. The aim of this work is to explore potential improvements of methods to estimate chemical emissions from consumer products. One possible improvement is the consideration of more variables like age, education level and ethnical origin when disaggregating products sales data at smaller spatial resolution. Another possible approach for estimating the amounts of chemicals released to the environment is to use average product consumption data from consumer surveys thus accounting for differences in consumer behaviour (bottom-up approach). Both approaches define the amount of product used per time which can be expressed in form of a probability density function. In a second step, the inclusion levels of chemicals are derived from the chemical composition of single consumer products. Finally, these values are used to estimate probability density functions of chemicals emitted to the environment. This work focuses on countries for which data is available for laundry products and shampoo, e.g. the European Union, the U.S., India and China. The chemical emission estimation techniques derived from this work can be used to derive global chemical emission maps. These maps can be used both for risk assessment and when conducting life cycle assessments of consumer products.

MO212

Urban modelling for engineered nanoparticle emission estimation: York case study

P.D. Núñez, University of York / Environment; A. Boxall, University of York / Environment Department; A. Praetorius, University of Vienna / Department of Environmental Geosciences

Urban pollution has become one of the main threats to human health in developed and developing countries. While half of the world's population already lives in cities, predictions of urban population growth are estimating 2.5 billion more inhabitants by 2050 (UN, 2014). As populations rise in urban areas there will potentially be an increase in the emissions of contaminants to the environment. These emissions will include novel and non-regulated contaminants such as engineered nanoparticles (ENPs). A wide variety of ENPs are already integrated in many different commercialized products such as cosmetics, fuel additives, paints and coatings and will be released to the aquatic environment following use and during disposal (Nowack et al. 2012). These ENPs vary in composition, shape, size and surface coating, which will determine their fate and behaviour after use. At the same time, environmental conditions such as pH, salt composition and presence of natural organic matter will also influences their behaviour and fate. All these factors make the exposure estimations a complex issue. However, the use of models can help us to better understand this complex systems and to fill data gaps where monitoring data is not yet available (Praetorius et al. 2013). In this context the aim of this project was to develop a realistic, small scale model for the prediction of environmental concentrations of several ENPs in urban surface waters. By using local specific data on the use and disposal of commercialised ENP-containing products, jointly with high resolution data of the water chemistry and the physical characteristics of the studied area, we are able to realistically predict the local exposure to these nanomaterials and to estimate their potential impact on urban ecosystems by mapping out exposure hots spots. The high resolution local model for ENP exposure in urban areas was developed by combining two individual but interconnected models: an emissions estimation model and a river model. A multimedia box model approach was used. The emission estimation model includes two main pathways of emission of the ENPs (i.e. via the sewage system and direct run off from field and roads). Emission estimates are obtained at high spatial resolution and are fed into the river model, where different processes, such as hetero-aggregation and sedimentation, are simulated and a final estimate of ENPs exposure is obtained.

MO213

Predicting wastewater treatment plant emissions of pharmaceuticals

L. Lautz; J. Struijs, Radoud University; D. van de Meent, R. Van Zelm, Radboud University / Department of Environmental Science

Due to the increased use of human pharmaceuticals, emission of those substances into the environment have been become a major concern. After consumption, pharmaceuticals and some of their metabolites ends up in wastewater and wastewater treatment plants (WWTPs). Not surprisingly, concentrations higher than 0.1 µg/L have been detected in WWTPs. Because many compounds are incompletely transformed in WWTPs, they are discharged into the environment via effluent water and sludge, which forms a potential risk for humans and ecosystems. Therefore, understanding and predicting the fate of pharmaceuticals through WWTPs is important. SimpleTreat is a simple box model that estimate the relative emission of a chemical from a WWTP to the environment. The model has become accepted as an evaluation tool for generic exposure assessment of substances emitted via sewage treatment plants in the European Union. Recently, the model was adapted to ionized substances and provided with new equations for a higher variability in operation parameters. In this study, it is tested whether the fate and elimination of pharmaceuticals are well predicted by the improved SimpleTreat 4.0. Variabilities in predictions are explained. Field data obtained from literature, which are measured in activated sludge WWTPs, were used. This search yielded measured concentrations of 51 pharmaceuticals in 34 different WWTPs. The modelled concentrations of SimpleTreat 4.0 were compared to observed effluent concentrations and chemical emission rates as derived from reported influent concentrations. The model predicts well in a number of cases. However, monitoring data are in some cases contrasting, due to variations in the operating system itself, like additional steps in treatment, which are not included in SimpleTreat. Next to this, differences in detection techniques and the time between sampling and measuring, can cause variability in data, because biodegradation still takes place, which especially can influence the measured effluent concentrations. Furthermore, the chemical-specific data related to ionizing properties of certain pharmaceuticals are uncertain, leading to divergent model outcomes.

MO214

A Model for assessing the fate of contaminants in constructed wetlands

S.E. Al-Marri, Analytical Environmental Chemistry; C.S. Warren, ExxonMobil Research Qatar / Environment and Water Reuse Program

INTRODUCTION Qatar is an arid country with limited amount of natural freshwater resources. As the population, community infrastructure and economy continue to expand there is a growing need for water resources for many domestic, agricultural, green space and industrial uses. There is currently a heavy demand on desalination of waters from the Arabian Gulf, however, there is value in looking at other potential sources of water to help meet the increasing demand. One such source may be industrial wastewaters that could be treated and beneficially used, particular for non-potable purposes. Produced water from the oil and gas industry represent large volumes of treatable water. At ExxonMobil Research Qatar (EMRQ), we are exploring the potential to use engineered wetlands, also known as constructed wetlands, to treat produced water. There are multiple examples of the use of engineered wetlands to treat industrial wastewater in the Gulf Cooperation Council (GCC) countries. Constructed wetlands typically consist of water flowing through a matrix of soil or sediment substrate consisting of living plants and associated microbes. The systems can be designed in various orientations, such as surface flow or subsurface flow, depending on the desired contaminant treatment and water characteristics. There are a number of biological and chemical processes that result in the sequestration, breakdown, evaporative loss and/or transpiration of contaminants. A significant amount of the activity occurs in the rhizosphere region and depending on the oxic or anoxic state of the system, different biochemical reactions will occur. These systems are designed to maximize removal of contaminants in water flowing out of the system. Consequently, it is important to have a good understanding of the contaminants to be treated and how best they can be treated. An effective approach to help understand constructed wetland behavior and the resultant fate of contaminants is to utilize mass balance models specifically built with the various wetland processes in mind. MASS BALANCE MODEL OF CONSTRUCTED WETLANDS EMRQ, with collaboration of Simon Fraser University (Canada), has developed a simple model for the environmental fate of contaminants in constructed wetlands, with the ultimate goal of aiding in the design and monitoring of engineered wetlands to support treated wastewater use applications. This is a preliminary model that has not been tested with field-generated data and, thus, is applied in an illustrative fashion. Regardless, the model is useful as an evaluative tool for exploring the potential treatment of different types of contaminants, ranking treatment effectiveness among contaminants groups, and identifying parameters or processes that are important to understand in more detailed to build more representativeness into the model. With time and application to field data, the model may be used to help design similar systems, understand their inner workings and also potential mitigations required to ensure the safe and effective use of the wetland across its lifetime of operation. The model has been developed with modules for: (i) environmental distribution of contaminants in aquatic system; (ii) uptake, translocation and biotransformation of contaminants in vegetation; (iii) bioaccumulation in aquatic biota of wetlands; and (iv) risk evaluation of contaminant toxicity to resident biota. The model computes both steady-state and time dynamic results of the mass and concentrations of contaminants in the wetland. The wetland model is currently able to simulate free surface flow, horizontal subsurface flow and vertical subsurface flow wetland configurations. Model inputs include wetland characteristics (e.g., compartment volumes, dimensions, organic carbon content, biotic growth rates); environmental conditions (e.g., water flow and temperature); and contaminant properties (e.g., molecular weight, degradation half-lives). MODEL ASSUMPTIONS This model is based on some key assumptions. First, it is assumed that the chemical is homogeneously distributed within each of the wetland media (e.g., water, sediments, plants) and that the wetland media can be described as single compartments in its exchange with its surrounding environment. It is recognized that this is an over simplification and that in particular there is likely to be a significant concentration gradient within the different media near the water intake location compared to those same media nearest the outfall. Realistic contaminant exchange between media will be further complicated by this effect. However, for our purposes as stated above, this is a reasonable assumption to make for such a preliminary model. A second key assumption is that the rhizomes are part of the vegetated rooting medium and in equilibrium with the rooting medium. This assumption may be reasonable for many organic contaminants and nonessential metals but not for essential nutrients such as nitrogen and phosphate. The model further assumes that vegetation can increase in biomass, which reduces the chemical concentration but causes no net loss of the chemical from the wetland. While these assumptions may be clearly gross simplifications of reality, they are reasonable first approximations for this screening level tool. **\n** MODEL APPLICATION To run the mass balance model for each of the wetland types mentioned above, the user must first identify the system dimensions, particularly the surface area (footprint) of the various media, water and sediment compartment depths and intake wastewater flow rate. There are a number of other process specific parameters (e.g., media diffusive exchange rates, media biodegradation rates, etc.) that need to be specified. At the moment assumptions have been made about these parameters on the basis of other studies. In some cases the values associated with constructed wetlands may be quite different from what is seen in nature and thus this adds another layer of uncertainty to the model. With time, addressing the more accurate representation of these values will be important for real world applications. Engineered wetlands are commonly designed to accommodate a combination of species of submerged, emergent, and floating vegetation. This promotes stronger microbial diversity by allowing vegetation coverage over different water depths. Typically, emergent species are the most common vegetation species in wetland design because they are involve in most of the processes in constructed wetland. Some of the key parameters associated with these plants will be surface area coverage density, growth rates, contaminant update, removal processes and storage capacity. Again, these and other plant input data will be based on previous studies. This may be particularly important for our application in Qatar as the climate conditions are likely to result in extreme representations of these parameters. Field-based plant-specific studies will be needed in the future to help derive more realistic values for our purposes. In addition to plant uptake and fate transport processes, the model also includes the functionality to include other lower order organisms (e.g., phytoplankton, zooplankton, benthic invertebrates) and fish to determine how contaminants may have an impact in the wetland system. This bio-uptake / bioaccumulation module draws upon extensive experience in the field of food web dynamics and ecotoxicology and provides another interesting layer of detail to a system that is known to become relatively diverse in nature and also depend on some of these organisms to maintain its health and effectiveness. Finally, the model has been developed to examine a suite of oil and gas relevant contaminants. Representative constituents of volatile, semi-volatile and polycyclic aronmatic hydrocarbons can be modeled. It is possible to examine other ionizable organic compounds such as Naphthenic acids. Metals can also be modelled in the system. In each case the model will require information on the physicochemical attributes of constituent that will help determine its ability to transport between media and be sequestered or transform in a media. Ecotoxicity data will be necessary to determine at what concentrations of each constituent effects on microbes, plants and other organisms may be seen. REPRESENTATIVE ANALYSES Three representative wetland orientations (free surface flow, subsurface vertical flow and subsurface horizontal flow) were modelled using a non-ionizable organic, an ionizable organic and a metal constituent to show the functionality of the mass balance modeling tool. Differences in the ability of each wetland to remove each contaminant from the wastewater stream can be expressed. The removal fraction of each constituent is estimated for the various processes, both at steady state and with time using the dynamic analysis. The steady state analysis provides a good indication of the anticipated removal efficiency in the wetland and the ability to quickly compare removal processes across contaminant constituents and across different wetland systems. This is quite helpful for comparison and ranking purposes. The temporal simulation provides the benefit of predicting the time-variable loading of constituents in media which may provide some indication of the timing required for remedial action in the system (e.g., plant harvesting once the holding capacity is met and removal efficient significantly declines; metal toxicity to microbes in the sediment/rhizosphere). This too is beneficial specifying the design of the system and determining the cost-benefit analysis of different approaches and systems. CONCLUSION Because there are currently insufficient data to conduct an actual model performance evaluation, the model has only been applied in an illustrative fashion. This application aims to demonstrate some of the key model features. The model may be most useful in evaluating the relative treatment capacity of wetlands for certain contaminants where certain contaminants are removed efficiently while others will be largely unaffected by wetland treatment. The model can also illustrate the relative importance of various chemical removal mechanisms for particular contaminants and illustrate the relative capacity of wetland treatment for different contaminants depending on substance and wetland properties. Also, model results provide insights into the temporal response of contaminant concentrations in wetland media and resulting contaminant concentrations in different wetland media. Finally, it may help to assess if the buildup of concentrations in the wetland media can pose ecotoxicological concerns for resident macrophytes, micro-organisms, invertebrates and fish that inhabit the wetland. Such evaluations are regularly used in environmental assessments of commercial chemicals and may also be useful in assessing the potential of wetlands to treat contaminated wastewaters. The ability of wetlands to treat contaminated wastewater is highly dependent on the contaminants and wetland characteristics. While some contaminants will be efficiently removed from wastewaters by the wetlands, others will be minimally affected. The models may therefore be useful in the planning and design of engineered wetlands. The models can make estimates of contaminant removal efficiency of the wetlands throughout their lifetime and predict whether wetland treatment can be expected to produce effluent streams that meet health and environmental standards. They can also be used to investigate key wetland design specifications such as size and vegetation type and flow patterns. Furthermore, they may also help indicate if certain chemicals in the wastewater stream will need special treatment approaches to affect their removal. It is important to emphasize that this is a preliminary model that has not been field tested. Currently, confidence in the model results is based on past applications of similar models to assess the multimedia environmental distribution, exposure and risk of contaminants in other contexts than engineered wetlands. These experiences provide a rationale for further testing and refining of the engineered wetland model presented in this study. With future efforts in model parameterization and performance analysis, the model may become more useful as a predictive tool for assessing the remediation capacity of contaminants using various engineered wetland designs. It is recognized that future work should include the evaluation and testing of the model capability to predict these various scenarios using field data. This type of assessment would help highlight gaps and future areas of study. Subsequently, this tool should provide valuable insights that can guide further studies for designing and monitoring the effectiveness of engineered wetlands for wastewater reclamation purposes. **\n**

MO215

Human exposure to household surface cleaning products: Application of a two-field model

G. Wang, University of Michigan / Environmental Health Sciences; L. Huang, University of Michigan / Dept of Environmental Health Sciences; O. Jolliet, University of Michigan

Indoor cleaning activity is a major human household activity and cleaning products contain volatile organic compounds (VOCs) that constitute a potential threat to indoor air quality and occupants health [2]. The overall objective of this study is to evaluate the short-term human exposure to household cleaning products. More specifically we aim 1) to establish a dynamic modelling framework which accounts for the near-person inhalation and dermal exposure to indoor cleaning products; 2) to determine the evolution of chemical mass and concentration associated with indoor cleaning activity, and to determine the key factors affecting chemical fate and exposure for indoor environment; and 3) to determine the short-term human intake, intake fraction (iF), and product intake fraction (PiF). We modify a two-zone model to describe the near-person and the far-person field identifying four transfer compartments, i.e. near-person surface, near-person air, far-person surface, and far-person air. Transfers between compartments are described by first order transfer rate constants structured in a matrix (K matrix) to describe the mass flows between different. The exposure matrix (XP matrix) relates the mass in a given environmental compartment to the intake by human. Eigenvectors and eigenvalues of the K matrix to simulate the dynamic behavior of the chemical mass in each compartment and variations in human intake through different exposure pathways. For both chemicals, mass in each compartment reaches its peak at 1.5 hour, at the end of the application phase. Of special interest is the contrast in mass evolutions between high and low volatile chemicals. For benzene the two air compartment tends to have the largest mass of chemical after the products is applied, whereas the mass on the near- and far-person surfaces are also high for 2-butoxyethanol. For both chemicals, inhalation exposure dominates the human intake during application phase. Compared to low volatile chemicals (2-butoxyethanol), dermal uptake is negligible for high volatile chemicals (benzene). The adapted two-zone model and its dynamic version using eigenvalues and eigenvectors enables us to describe well and with parsimony the dynamic of masses and intakes. The presentation further details and contrast the time evolution and the resulting intake fraction and product intake fraction for the 21 considered substances.

MO216

Evaluation of models for gas-particle partitioning of nitro- and oxy-aromatic hydrocarbons

P. Shahpoury, Max Planck Institute for Chemistry / Multiphase Chemistry; G. Lammel, Max Planck Institute for Chemistry; A. Albinet, INERIS; Z. Kitanovski, Max Planck Institute for Chemistry; S. Tomaz, INERIS; E. Villenave, E. Perraudin, Université Bordeaux / EPOCCNRS; C. Rizzi, University of Milano Bicocca

Gas-particle partitioning is an important mechanism affecting the transport and fate of semi-volatile organic compounds (SOCs). The preferential partitioning of SOCs in the atmosphere depends on parameters such as the compound's molecular structure as well as particulate matter physical and chemical properties. This can be explained by various empirical and theoretical models based on single- or poly-parameter linear free energy relationship (ppLFER). To explain the SOC partitioning, each model considers one or more of the compound's physico-chemical properties or particulate matter characteristics. Despite the past efforts in determining the most appropriate model, discrepancies remain between the model prediction and observation because some models neglect certain intermolecular interactions. The aim of the present research was to apply a dual-phase as well as a multi-phase ppLFER model to predict gas-particle partitioning of nitro- and oxy- aromatic hydrocarbons. To this end, air samples (gas and particulate phase) were collected from urban and non-urban sites in Germany, France, and India. The poster will present the model predictions versus observations, and discuss their structural differences in details.

SimpleBox4nano, A Screening level Environmental Exposure Model for Nanoparticles: Analysis of TiO2, Ag and C60

J.T. Quik, RIVM / DMG; E. Tsitsiou, National Institute for Public Health and the Environment RIVM; J. Meesters, Radboud University Nijmegen / Environmental Science; D. van de Meent, RIVM / DMG

In order to sustain the development of nanomaterials by industry, a robust risk assessment framework is needed. A screening level environmental exposure model is one of the first steps of such a framework currently in place in Europe and the United Sates, but this needs adaptation for use with nanomaterials. We incorporated the SimpleBox4nano model definition previously published into the Simplebox model currently implemented in EUSES as part of REACH. This is a nested multi-compartment multi-scale model that can predict exposure concentrations (PECs) for 4 different chemical species in the environment. We use this model to show the uncertainty of estimating PECs for TiO2, Ag and C60 nanoparticles (nPs). These nPs represent three common nP types, being a poorly soluble metal oxide, a readily soluble metal and an insoluble carbonaceous nP, respectively. The default scenario of SimpleBox v4 is used, which includes the Rhine catchment, Europe and the whole Northern hemisphere. In order to assess the uncertainty of the steady state PECs we conducted a probabilistic assessment based on the uncertainty in nano specific input parameters. The variability and uncertainty of other parameters was not included due to this being similar for conventional chemicals and is expected to currently be at an acceptable level for screening purposes. The results show that the variation of the obtained PECs can be explained largely by the uncertainty in the emission rates. Other important parameters explaining the variation in PECs are (i) the uncertainty in the attachment efficiency between nPs and natural colloids and other particulate matter. And (ii) the dissolution rate of nPs. It was found that the dissolved species of nPs reached very high concentrations in certain environmental compartments, this is however due to the low removal rates from these compartments. The concentrations were much lower when considering the 1 year PECs calculated using the dynamic module of SimpleBox4nano. This suggests that for regulatory purposes, time dependant PECs might be more relevant than steady state concentrations in exposure assessment of nPs.

MO218

A risk management model for evaluating the impact of sediment resuspension on the distribution, bioavailability and toxicity of harmful contaminants in the port of Antwerp and Scheldt Estuary

H. Hetjens, SPHERE / SPHERE; J. Teuchies, R. Blust, University of Antwerp / Systemic Physiological and Ecotoxicological Research Department of Biology

The port of Antwerp is Europe's most central and second largest sea port, ranking second behind Rotterdam by total freight shipped. It is a cluster of industry and marine and road traffic in a densely populated area. Present and historical activities have caused the contamination of sediment and water and led to a moderate to low water quality within the harbour docks. Under undisturbed circumstances the impact on water quality of contaminants fixed in the sediment layer is relatively low, but has been investigated to increase significantly when contaminated sediments are resuspended. In order to maintain or improve the current water quality of the Port of Antwerp as well as the connected Scheldt estuary areas, the aim of the present project, which is part of EcoDocks+, a cooperation between the Antwerp Port Authority and the University of Antwerp, is to develop a dynamic risk management model for contaminants under disturbance in the aquatic environment. With this model the main sources for sediment resuspension within the port area will be determined and the re-accumulation behaviour of contaminants in the water phase investigated. It is expected that sediment resuspension and transport and therefore the distribution, bioavailability and toxicity of harmful contaminants is mainly caused by three major factors (1) advective sediment flux through the sluices, (2) ship traffic and (3) dredging activities. In the coming four months, existing literature and data sets as well as the results from own measurements will be used to develop a user friendly interface that can be used to calculate the short and long term changes in concentrations of contaminants in water and sediment layers during and after resuspension and to determine the effect size on the aquatic environment of each of the three factors. In the future, our results and the model itself can be used to identify areas with high risk potential and evaluate possible risks of future maintenance or construction works on harbour sediments on current water quality status.

MO219

Does the inclusion of mass balance and degradation processes to vegetative filter strips impact long-term pesticide environmental exposure assessments?

A. Ritter, Waterborne Environmental, Inc.; R. Muñoz-Carpena, University of Florida / Department of Hydrology Water Quality Agricultural Biological Engineering Faculty; G. Fox, Oklahoma State University / Biosystems and Agricultural Engineering; O. Perez-Ovilla, Bayer CropScience LP

Vegetative filter strips (VFS) are a widely adopted for reducing pesticide transport from adjacent fields to receiving water bodies. The long-term VFS efficacy is dependent on site-specific factors related to soils, weather, land use, vegetation and maintenance. The previous version of the well-tested process-based model for VFS (VFSMOD), assumed that pesticide mass stored in the VFS was not available for transport in subsequent storm events. This research study uses an updated PRZM/VFSMOD/EXAMS modeling framework, by considering the effect of the addition of surface mass balance and four options of degradation processes on acute (peak) and chronic (60-d) aquatic environmental exposure concentrations (EECs) and percent reductions across three distinct 30-yr US EPA scenarios. Global sensitivity analysis (GSA) was used to assess the relative importance of adding or removing mass balance and degradation processes in the context of other important input factors like VFS length (VL), pesticide organic-carbon sorption coefficient (Koc), and half-lives in both water and soil phases. It was concluded that considering degradation in the VFS was not relatively important if single, large events were controlling the transport process, as is typical for the higher percentiles considered in standard exposure assessments. Degradation processes become more important when considering percent reductions in acute or chronic EECs, especially under scenarios with lower pesticide losses.

MO220

Development of a scoring system for surface soil pollution potential of chemicals from accidental release by using a multimedia model SoilCCA

K. Kim, J. Jung, Seoul National University; Y. Lee, L. Chang, Seoul National University / Dept of Environmental Studies; D. Lee, Seoul National University / Environmental Planning Institute Graduate School of Environmental Studies

Hazardous chemicals accidentally released into air can transfer to surface soil by dry and wet depositions, leading to surface soil pollution which can adversely impact the soil ecosystem. A new scoring system was developed to evaluate the surface soil pollution potential of chemicals accidentally released into air. Scores for surface soil pollution potential of individual chemicals were to be determined by multiplying three indicators i.e., level of pollution, persistence of pollution, and spatial extent of pollution given a unit quntity (1 ton) of release. A new dynamic mutimedia model named SoilCCA was developed to calculate the scores. SoilCCA consists of a toal of 3100 cells to cover an area of 15 km (L) x 3 km (W) as a model domain. Each cell is of a 150m x 150m x 1000m size with three comparments, i.e., air, surface soil, and vegetation. The temporal and spatial concentration change in surface soil was investigated for five typical types of chemical release. It was found that the concentration profiles with time and space were practically independent of the release type with a difference only in the concentration level and the rate of decrease of the concentration among the chemicals. From the findings, the three equations were derived to calculate the indicators; i) pollution level as represented by the average concentration, ii) persistence of pollution by the slope of linear relationship between logarithm of the surface soil concentration and time, and iii) spatial extent of pollution by logarithm of the maximum concentration in surfac soil. About 600 chemicals in the list of "Toxic Chemicals Control Act" of Republic of Korea will be evaluated for their surface soil pollution potential.

MO221

Evaluation of accidentally released chemicals for their surface soil pollution potential by using SoilCCA

K. Kim, J. Jung, Seoul National University; Y. Lee, L. Chang, J. Park, Seoul National University / Dept of Environmental Studies; D. Lee, Seoul National University / Environmental Planning Institute Graduate School of Environmental Studies

Hazardous chemicals accidentally released into air were evaluated for their surface soil pollution potential. Scores for surface soil pollution potential of individual chemicals were to be determined from three indicators (level of pollution, persistence of pollution, and spatial extent of pollution given a unit quntity (1 ton) of release) by using SoilCCA. About 600 chemicals in the list of "Toxic Chemicals Control Act" of Republic of Korea were evaluated. Heavy metals and semi-volatiles generally showed higher scores than VOCs, which was qualitatively anticipated prior to the evaluation. Chemicals of the greatest surface soil pollution potential include heavy metals and semi-volatile organic compounds such as benzo(a)pyrene as their wet deposition flux and sorption capacity onto soil particles are high while the loss rates by diffusion to air and surface run-off are low. For the organic compounds evaluated, only the indicator for the spatial extent of pollution showed negative correlations with the Henry's law constant exceeding a certain value depending on the chemical groups. The low pollution potential of VOCs can be accounted for primarily by their high vapor pressure and Henry's law constant. Of particular use of SoilCCA was made of evaluating organic compounds that belong to neither semi-volatiles nor VOCs, which would not readily be done without a quantitative tool.

MO222

Monitoring and modelling of POPs in air at Cape Verde, Africa

T. Nøst, A. Backlund, NILU - Norwegian Institute for Air Research; S. Eckhardt, NILU - Norwegian Institute for Air Research / Atmosphere and Climate Change Department; A. Halse, NILU - Norwegian Institute for Air Research; M. Schlabach, NLU - Norwegian Institute for Air Research; K. Breivik, Norwegian Inst. for Air Research

Ambient air is among the core media selected for the sampling and analysis of Persistent Organic Pollutants (POPs) under the Stockholm Convention. Ambient air also provide useful information for (i) studies of global transports of POPs, and (ii) atmospheric sources and source regions. Yet, existing data on POPs in air based on active air sampling remain scarce and mainly limited to industrialized regions in the northern hemisphere. The primary objectives of this study were to (i) monitor concentrations of selected POPs in air outside West Africa, and (ii) to evaluate sources and source regions affecting measured concentrations. For this purpose, an active high-volume air sampler was installed on The Cape Verde Atmospheric Observatory (CVAO: 16.848°N, 24.871°W), a World Meteorological Organization (WMO) global station at Cape Verde outside the coast of West Africa. Sampling commenced in May, 2012 and 43 samples were collected until June 2013 (24 h sampling). The samples were analyzed for selected polychlorinated biphenyls (PCBs), polybrominated diphenyl ethers (PBDEs), hexachlorbenzene (HCB) and chlordanes. The source regions of the air masses were evaluated for each sample using the FLEXPART model. FLEXPART is an atmospheric Lagrangian transport model, developed by Andreas Stohl and co-workers, which calculates the trajectories of so-called tracer particles (flexpart.eu). It was run in backward mode, in order to identify the source regions of air pollutants at a particular site. A general finding is that the concentrations measured are in the lower range in comparison to data from the literature, which is mainly attributed to the remoteness of the station from major sources and source regions. Factors controlling measured concentrations will be evaluated and discussed.

MO223

Modelling the behavior of cyclic volatile methyl siloxanes in an Arctic benthopelagic freshwater food web

I.S. Krogseth, Norwegian Institute for Air Research / Environmental Chemistry; E. Undeman, Stockholm University / Environmental Science and Analytical Chemistry ACES; A. Evenset, G. Christensen, Akvaplan-niva AS; M. Whelan, University of leicester / Geography; K. Breivik, Norwegian Inst. for Air Research; N.A. Warner, NILU - Norwegian Institute for Air Research / Environmental Chemistry

Cyclic volatile methyl siloxanes (cVMS) are used in personal care products and are emitted to aquatic environments through wastewater effluents. Due to the high hydrophobicity of cVMS, sediments are expected to be an important source for biotic exposure in benthic and benthopelagic food webs. However, details of the exposure pathways have yet to be fully understood. The main objective of this study was to explore the role of the sediment compartment for bioaccumulation of cVMS in an Arctic lake (Lake Storvannet, 70 °N 23 °E) through a combination of modelling and measurements. Storvannet is an oligotrophic lake with ice-cover for 6 months of the year and a short summer season. Food webs for resident Arctic Char (*Salvelinus Alpinus*) and Brown Trout (*Salmo Trutta*) are strongly connected to the benthic community. Sediment, benthos, and fish were collected and analyzed for cVMS concentrations in 2014. Concentrations of decamethylcyclopentasiloxane (D5) were comparable to concentrations found near more highly populated areas, and were significantly higher in muscle tissue of Arctic Char (3.8 ± 2.8 µg/g lipid) than Brown Trout (0.8 ± 0.6 µg/g lipid). Higher values of $\delta^{15}N$ in Brown Trout (12.4 ± 0.9) than in Arctic Char (10.4 ± 1.0) indicates trophic dilution, but their different cVMS concentrations may also be influenced by species-specific differences in behavior or biotransformation. To rationalize the measured concentrations, a mechanistic pelagic bioaccumulation model (ACC-HUMAN) was modified to incorporate benthic exposure. The model was specifically parameterized for key benthic species (the deposit feeder *Chironomidae* sp. and the filter feeder *Pisidium* sp.) and fish, including time-variant uptake and elimination processes for ventilation, feeding, growth, egestion and biotransformation. Measured concentrations in sediments and modelled concentrations in water were used as input to the model. Preliminary simulations show that incorporation of a benthic link in ACC-HUMAN can be important to rationalize not only observed concentrations, but also cVMS oligomer patterns in fish. The model was used to explore the influence of different dietary scenarios, as well as observed concentration differences between Arctic Char and Brown Trout. This model-measurement comparison helps to both evaluate the new benthic ACC-HUMAN model and to contribute new insights into the trophic transfer of cVMS in benthopelagic ecosystems.

MO224

Critical review and interpretation of environmental data for volatile methylsiloxanes: Monitoring cVMS in non-biological media

S. Xu, Dow Corning Corporation / Health and Environmental Sciences; N.A. Warner, NILU - Norwegian Institute for Air Research / Environmental Chemistry; J.A. Durham, Dow Corning Corp. / Health and Environmental Sciences; D.A. McNett, Dow Corning Corporation / Health and Environmental Sciences

Due to their heavy use, cyclic volatile methylsiloxanes (cVMS) are under increased regulatory and scientific scrutiny. In last few years, the fate, transport and distribution of these compounds have been studied both by multimedia environmental fate modeling and also by the environmental monitoring. The objective of this project was to compare the monitoring results of cVMS with their model predictions and to identify the critical data gaps in our understanding of the major environmental processes regulating the transport and distribution of cVMS in the total environment. The published modeling assessments included both simple steady state simulations and time variable analysis at local, continental and global scales using both hypothetical and realistic release scenarios. The non-biological media studied in the disclosed environmental monitoring programs included air, soil, water and sediment mostly in regions impacted by human activities with some from remote Polar Regions. The temporal and spatial patterns of cVMS concentrations in air, soil and sediment, were generally in a good agreement with the modeling predictions with exception to a recently published findings in Antarctica. The biggest inconsistency with the model predictions was the concentration ratios of various cVMS measured at different locations. This highlights that future work is needed to develop monitoring methods which can prevent samples from contamination and to minimize artifacts and misinterpretation in reporting cVMS environmental behavior including the concentration ratios.

MO225

Temporal-spatial fate of cesium-137 in terrestrial environment around Fukushima Daiichi Nuclear Power Plant: a challenge for daily simulation

Y. Imaizumi, K. Kuroda, Y. Morino, S. Hayashi, N. Suzuki, T. Ohara, National Institute for Environmental Studies

About five years has passed since the accident of the Fukushima Daiichi Nuclear Power Plant (FDNPP). Topic of interest has shifted from analyzing the current situation of radioactive pollution to predicting the future situations of radioactive pollution especially of cesium (Cs)-137. Previously, we reported simulation results of terrestrial environmental fate of Cs-137 in Japan about 10 years after the accident, using the multimedia environmental fate model (Grid-Catchment Integrated Multimedia Modeling System, G-CIEMS). Based on this simulation result and published researches, it was revealed that major part of Cs-137 had deposited to forest area, most of Cs-137 strongly attached to soil surface after the deposition, and therefore Cs-137 would slowly run off from the forest area. Several researchers reported that outflow of Cs-137 to the ocean predominantly occurred during typhoon Roke September 21, 2011. Therefore, in this study, we improved our model in order to simulate daily change of environmental conditions and related fate of Cs-137. To achieve this goal, we 1) calculated amounts of direct deposition of Cs-137 to surface waters (rivers and lakes), 2) calculated daily amount of soil runoff from land area by using Universal Soil Loss Equation (USLE), 3) set up daily river flow rate, and 4) calculated daily suspended solid (SS) concentration in river. As the first step, we made polygon data of surface water segments which were used in our model, calculated the area of each surface water segment in each 1-km mesh, and then calculated amounts of direct deposition of Cs-137 to each surface water segment. As the second step, we calculated daily “rain factor” used in USLE using 30 minutes precipitation data for each 1-km mesh, and then calculated daily soil loss from land by erosion. As the third step, we set up daily flow rate of each river segment based on daily precipitation and simple assumptions. As the fourth step, we calculated daily SS concentration in each river segment using daily input amounts of SS (= soil loss from dry land) and mass balance equation of SS. We simulated annual fate of Cs-137 in Abukuma river basin and river basins in Hamadori region, the surrounding area of the FDNPP, and obtained good agreement between simulated flux of Cs-137 and field observations.

MO226

Long-term and large-scale prediction of air radiation dose rate in Fukushima: incorporating vertical migration of radioactive cesium

K. Kuroda, Y. Imaizumi, National Institute for Environmental Studies; M. Takagi, National Institute for Environmental Studies / Centre for Environmental Health Sciences; N. Suzuki, S. Hayashi, T. Ohara, National Institute for Environmental Studies

Long-term prediction of air radiation dose rate is important in Fukushima, Japan, where a large amount of radioactive cesium was deposited following the accident of Fukushima Dai-ichi nuclear power plant in March 2011. In general, air dose rate derived from deposited radioactive cesium is known to decline with time, not only because of natural decay, but also because of various processes, including migration of cesium into deeper soil. The rate of decline excluding natural decay would vary depending on locations and other factors. To date, however, there has been no comprehensive study on this. In the present study, we evaluated the effect of radioactive cesium migration on the decline of air dose rate in a large area, using various geo-referenced and time-course data of deposition and soil depth-profile of radioactive cesium and air dose, which have been published since the nuclear accident. The decline of air dose rate was evaluated, after eliminating the effect of natural decay, as the temporal change of conversion coefficients between the depositional radioactive cesium amount and the air dose rate measured at 1 meter above the ground. The soil migration of radioactive cesium was evaluated by the temporal change of weighted center obtained from the depth profile. The results showed that the conversion coefficient decreased with time and with depth, although a large variation was noted on the temporal change. Finally, we predicted the long-term change of air dose rate in the large area of eastern Japan, considering the effect of migration of radioactive cesium on the conversion coefficient. Our study highlights the importance of vertical migration of radioactive cesium for a better spatiotemporal prediction of air dose rate.

MO227

A Global Historical Inventory of Individual PBDEs: From Production Towards Emissions

A. Golnoush, NILU Norwegian Institute for Air Research / Geography; K. Breivik, Norwegian Inst. for Air Research

Despite advances in environmental fate modeling, measuring and monitoring of persistent organic pollutants (POPs), knowledge about their sources and emissions remains a major knowledge gap. This mitigates our potential to understand and predict historical and future POPs concentrations in various environmental media. The first step towards estimating the global emissions of deliberately produced POPs and their future trends is to obtain an overview of their production and consumption on a global scale. In this study, we compiled data on the global production of three main commercial mixtures of PBDEs (penta, octa and decaBDE) from 1970, along with data on the chemical composition of these mixtures, in order to estimate historical production trends of selected individual PBDE congeners. The global consumption over time was next estimated from available information on use of PBDEs in different regions, per capita consumption and/or surrogate data. These results will be coupled with material flow analysis to estimate the amount of waste PBDE-containing products that are subject to transboundary movement. The results of this study will be used in a global emission model to estimate temporal trends of PBDE emissions at the global scale.

MO228
Environmental exposure assessment of sucralose in receiving waters at differing spatial scales
K.E. Kapo, R. Vamshi, M.L. Sebasky, Waterborne Environmental, Inc.; D.B. Huggett, Waterborne Environmental, Inc. / Department of Biological Sciences; C.M. Holmes, Waterborne Environmental, Inc.
Down-the-drain exposure models provide a valuable screening-level tool for estimating environmental exposure to product ingredients which are treated and discharged at municipal wastewater treatment plants. We present an environmental exposure assessment for sucralose, an artificial sweetener which ultimately ends up in the environment via down the drain emissions. Exposure modeling was performed using the iSTREEM® model, a publically-available web-based model supported by the American Cleaning Institute (www.istreem.org) which estimates spatially-explicit concentrations of chemicals in effluent and receiving waters across the U.S. at mean and low flow conditions. Wastewater treatment facility influent loadings of sucralose were estimated using per-capita usage derived from market sales volume combined with individual facility population served and daily flow estimates within the iSTREEM® model. The screening-level assessment used an assumption of zero removal during treatment and no in-stream decay, resulting in a representation of "worst-case" environmental exposure estimates. Three case studies of modeling at different spatial extents are presented: national scale of the continental U.S., regional scale of the Lake Erie drainage basin, and local scale of the Grand River Watershed in Canada. US-wide predicted environmental concentrations (PECs) estimated by the model at mean annual flow conditions were comparable to sucralose concentrations typically expected to be observed in the field, with a 90th percentile PEC in surface waters of approximately 1.9 μg/L. Watershed-scale modeling of the Grand River was compared to published data from 23 sites measured in 2007-2009. This local assessment was enhanced with temporally-specific adjustments to flow. Once time-specific gaging data were added, the model predicted a comparable exposure pattern to those measured across the 23 sites. Maps of the estimated geographic distribution of US-wide and Grand River watershed river concentrations are presented using geo-referenced concentration data generated by the iSTREEM® model. These screening-level environmental exposure assessments provide an estimated distribution of PECs in a spatial and potentially temporal context. These can be used to inform risk management and/or subsequent higher-tier assessment.

MO229
FlowEQ - a coupled flow-network and fugacity based fate and transport model for the assessment of Bisphenol A in the environment
M.J. Bock, M. Bunge, M. Vosteen, Ramboll Environ; I. Gutiérrez, BiPRO GmbH; J. Woelz, Currenta; P. Stoldt, Envigo CRS Switzerland Ltd; E.M. Mihaich, ER2; S. Gestermann, R. Werner, Covestro Germany AG
Substances used in consumer products can enter the environment as part of the manufacturing process or through the use and disposal of consumer products. These substances can be discharged through a number of different pathways such as manufacturing outfalls, domestic wastewater, and other emissions pathways. When these substances are discharged to surface water they have the potential to accumulate in aquatic environments depending on their physico-chemical properties. Many of these substances are infrequently characterized in aquatic environments due to inadequate analytical methods or the lack of their inclusion in monitoring programs. Furthermore, even a robust monitoring dataset often provides limited information on the relative importance of source pathways. The first step in the assessment of the potential impacts to the environment is an assessment of the concentrations in environmental media and the relative importance of the various source pathways. Models such as MORE/MONERIS have been developed to quantify emissions and model the resultant surface water concentrations using a flow network approach that utilizes a water balance/dilution methodology. This approach has been shown to provide accurate predictions for certain substances, but it does not model processes such as partitioning between various media and degradation. To address this limitation, we developed a hybrid fate and transport model that combines the dilution/water balance flow network of the MORE/MONERIS model with a level III fugacity based model (*FlowEQ*). Partitioning between media and degradation processes are easily included in fugacity based models. The *FlowEQ* model was populated with watershed information and emissions of Bisphenol A (BPA), a substance that degrades in the environment, to German watersheds. The model considered a wide variety of processes including industrial and per capita emissions, wastewater treatment, landfill leachate discharges, partitioning between environmental media, soil runoff, atmospheric scavenging, degradation, and the advective transport to downstream areas. Consumer emissions were found to dominate and the predicted surface water concentrations were consistent with those measured in surface water demonstrating the suitability of the *FlowEQ* model. The model can be further used to assess the relative importance of various substances and emissions pathways and explore how concentrations change as usage patterns and treatment technologies change.

Modelling of pesticides and biocides fate and exposure in a regulatory context (P)

Modeling honey bee extinction risk posed by neonicotinoid insecticide (imidacloprid) exposure
N. Hsieh, Department of Bioenvironmental Systems Engineering; C. Liao, National Taiwan University / Department of Bioenvironmental Systems Engineering
Colony collapse disorder has become an ecology crisis for honey bee population in recent years. Neonicotinoid insecticide is the suspected risk factor, which may accelerate the bee population decline. The most widely used insecticide in the world is imidacloprid that can harm honey bees through their pollinating of nectar and other consumes. The purpose of this study was to develop a risk-based population dynamic model and a probabilistic risk assessment framework to predict the potential hazards of imidacloprid toxicity toward honey bee population that may further casue colony collapse disorder.Published toxicity bioassay of imidacloprid exposure to honey bee mortality were be used as the study data. The nollinear regression models were used to reconstruct a dose-mortality response profiles in acute and chronic imidacloprid toxicity. We rebuilt the simple differential equation-based model built on previous study that can be used to simulate the seasonal dynamic of honey bee population and food storage based on the seasonality parameters of laying rate, mortality rate, and food consumption rate. This study also parameterized the imidacloprid toxocity to simulate the toxicity effect on honey bee population. Finally, we applied the probabilistic risk assessment framworktoassess the potential risk of environmentally relevant imidacloprid for hooney bee population. We further built the interactive web application by using Shiny for the R programming language that have the potential to revolutionize the sharing and risk visualization of population dynamic model simulations. This study provides the novel risk assessment concept to characterize the imidacloprid exposure risk to honey bee population. Current result showed that realisitc in-field exposure dose distribution of imidacloprid can only effect the honey bee population slightly. Moreover, the developed population dynamic model can be further extended to simulate and realize the other risk factors that may cause colony collapse disorder. The web-based interactive applications of risk visualization can help people understand the quantitative risk of imidacloprid toxicity.

MO231
Modelling of Acetamiprid residues as foliar application in pepper
C. Turgut, ADU; C. Şarkaya, Agricultural Engineering; M. Yalçın, Adnan Menderes University / Faculty of Agriculture; A. Rein, Technical University Muenchen
Pesticides are worldwide used to control pests, diseases and weeds of many crops. Although pesticide residues are regularly monitored and regulated, they are still detected above MRL (maximum residue level) in many countries. Many models have been developed to predict the residues in plants and crops for soil application and are not consider foliar application for the following pesticide application. Acetamiprid is a systemic insecticide applied to pepper plants twice in ten days intervals and collected pepper fruits 35 days long. Quechers method was used for extraction of acetamiprid and analysed by LC/MS/MS. The cascade model was adopted to foliar application to predict the pesticide residue over the period. The concentration of acetamiprid residues declined very sharply until second application. Simulated concentrations of residues were very similar to experimental results so that curve fitted well. The concentration in pepper reaches almost fifty percent of initial concentration after second application and decreased slowly in comparasion to first application. The calculated concentrations in fruit after second application were lower than experimental. This model has advantage to predict PHI (Preharvest Intervals) between applications to decrease acetamiprid residues in many crops.

MO232
Computer simulations of plant protection products on leaf surfaces at the nanoscale

M. Jochum; L. Garcia, Crop Protection; B. Gottesbueren, BASF SE / Crop Protection
Foliar applied plant protection products (PPPs) may be washed-off the leaf surface during rainfall events, leading to varying temporal exposure patterns of the pesticides on soil. Good descriptors of this process are, however, still missing due to a lack of understanding of the key factors involved. Thus, current environmental fate regulatory assessments for PPPs rely on worst case descriptors to account for the wash-off process. The objective of this work is to use molecular modeling to fill in the gap and allow for the establishment of higher tier refinements for environmental fate models. Using molecular dynamics simulations, we can elucidate the relevant interactions involved at the nano/micro-scale using coarse-grained models of the PPP's formulation components (active ingredients, dispersing agents, emulsifiers, solvents, etc.) and of the plant leaf surface. The leaf surface is simulated by a thick hydrophobic layer covered by a mixed polymer matrix of the main epicuticular waxes. The composition of this mix can be obtained from ATR-FTIR spectroscopy measurements for the specific plant of interest and thus characterizes the modeled interactions for the various types of crops under investigation. All coarse-grained models are based on the individual molecules' octanol-water partitioning. By examining how the individual formulation components are distributed on the leaf surface with respect to the aqueous phase of the PPP, we aim to estimate its wash-off potential.

MO233
Experimental determination of foliar wash-off factors as input for FOCUS exposure modelling
E. Hein, G. Reinken, Bayer CropScience AG
The foliar wash-off factor is a compound and product (formulation) specific modelling input parameter relevant for the aquatic exposure assessment after foliar application. To ensure a realistic worse case for soil residues, the foliar wash-off coefficient was originally set to a default value of 0.5 cm^{-1} for FOCUSsw calculations. EFSA proposed later a more conservative default value of 1 cm^{-1} if no experimental data are available. The use of measured refinement values for the wash-off fraction reflects specific compound behaviour and is part of FOCUS guidance and accepted by EFSA. Recently EFSA published a guidance document in which the foliar wash-off factor also needs to be considered for the soil exposure assessment. Thus, the foliar wash-off factor may be experimentally determined if a refinement is needed for the aquatic or soil exposure assessment of a specific compound. A generic frame work of an experimental study design has been derived in a workshop organised by the European Crop Protection Association (ECPA). This frame work was used for the experimental determination of wash-off factors for modelling purposes. The wash-off studies were conducted under GLP for different compounds of foliar applied products applying different rainfall scenarios. Four main conclusions could be derived from the presented measurements: The wash-off factor … → … is independent from the investigated crop and BBCH stage, if leaf surface properties are comparable regarding their respective wetting regimes. → … can be influenced by both the formulation composition and the physico-chemical characteristics of the active ingredient, in some cases strongly. → … is comparable for standard, non-optimized formulations where the nature of the deposits is similar (e.g. SC, WP and WG formulations). → … of optimized formulations (resistance to wash-off by rain) can be significantly reduced compared to standard formulations.

MO234
Exposure and Risk Assessment for operator exposure to Insecticide thiamethoxam during grape cultivation in vineyard using Whole Body Dosimetry
J. Lee, E. Kim, Seoul National University / Department of Agricultural Biotechnology; Y. Shin, Seoul National University; J. Lee, J. Lee, M. Jung, J. Sung, Seoul National University / Department of Agricultural Biotechnology; J. Kim, Seoul National University
Thiamethoxam belongs to the neonicoitinoid class of chemicals. It is broad-spectrum insecticides that are used to control a wide range of diseases in fruit and vegetables. Assessment for operator's dermal and inhalation exposure to thiamethoxam during cultivation of grape in vineyard was carried out. For dermal exposure measurement, whole body dosimetry (WBD) was performed in Korea. WBD consists of cotton/polyester outer clothes and cotton inner clothes. Hand exposure was measured by washing of nitrile gloves and hands while head exposure was monitored by face/neck wipe technique. Inhalation exposure was monitored with personal air sampling pumps and IOM sampler (glass fiber filter). Analytical limit of quantitation was 5.0 ng/mL. Good reproducibility (C.V < 7.6%), linearity ($R^2 > 0.99$) and recovery (75~113%) were obtained. Field recovery of thiamethoxam was 88~106%. Field experiments were carried out 11 replicates, and data was processed with 75 percentile statistical method. During application, total dermal exposure was 32277.0 µg, and that of mixing/loading case was 194.5 µg. During mixing/loading, hand exposure of thiamethoxam (156.4 µg) was slightly less than that of application case (519.3 µg). But considering the ratio of hand exposure to the total dermal exposure, mixing/loading hand exposure ratio (80.4%) was much higher than that of application (1.6%). During mixing/loading, all parts were similar density, but application case, exposure of thigh and shin was high density (47.0%). Penetration rate between outer and inner dosimeter was about 10%. Inhalation exposure during application (10.8 µg) was about 30 times more than that of mixing/loading case (0.3 µg). Margin of safety (MOS) was calculated for risk assessment using male Korean average body weight (70 kg) and acceptable operator exposure level (500 µg/kg/day) to give 7.3, suggesting that health risk of operator during treatment of thiamethoxam for grape in vineyard could be safe.

MO235
World Exposure Assessment Tools and Scenarios
A. Ritter, Waterborne Environmental, Inc.; M. Cheplick, Waterborne Environment; G. Hoogeweg, C.M. Holmes, Waterborne Environmental, Inc.
Modeling platforms have been developed to evaluate the potential impact of crop protection chemicals on the environment throughout the world. The tools currently have been configured with scenarios containing crop, soil, and weather conditions for major agricultural areas in Brazil, Canada, Colombia, the European Union, Norway, the People's Republic of China, and the United States. Additionally, agricultural scenarios have been developed for countries such as Peru, Ecuador, Taiwan, Philippines, and Korea. All these scenarios are simulated using fate and transport models that have been accepted for regulatory assessment in the U.S. and the European Union, including the Pesticide Root Zone Model (PRZM), Exposure Analysis Modeling System (EXAMS), Rice Water Quality Model (RICEWQ), and Toxic Substances in Surface Waters (TOXWA). Development of country specific scenarios and tools will be described. A key strength of the tools are that scenarios can be added for additional geographical areas with relative ease and the appropriate regulatory endpoints.

MO236
First industry experiences with the new exposure assessment guidance documents and models in China
H. Shbaita,
Since almost a decade ago, China has started to develop their own framework for the registration of plant protection products. A major building block of this framework is the guidance documents on environmental risk assessments. In total there are 6 (draft) guidance documents, aquatic (rice), groundwater, birds, bees, NTA and silkworms. These include two models for groundwater calculation (ChinaPEARL) and one for surface water paddy rice (TopRice). After the first commenting round in beginning of this year, in which CLC (CropLife China), the CERA team (Chinese Environmental Risk assessment) and CLI (CropLife International) provided more than 400 comments, the guidance documents have been updated and are now in the process of finalization (most probably, by the time the SETAC conference takes place, these guidance documents will be already published and came into force). ICAMA has given training using the final draft guidance documents to different stakeholder. This gives the ideal time point to report on the first experiences the industry has made using these "new" exposure assessment models and guidance documents. This includes comparison between EU and China PEARL, and also model testing for the TopRice model.

MO237
Modelling and monitoring travel distance of pendimethalin in air
B. Jene, J. Hassink, BASF SE / Environmental Fate
Based on the physical-chemical properties of pendimethalin volatilization can be a relevant dissipation pathway. Laboratory studies with pendimethalin SC and EC formulations showed significant volatilization from plant and soil surfaces. The travel distance in air is mainly influenced by the aerial half-life of pendimethalin which is estimated to be 4.2 hours (Atkinson calculations) and confirmed by experimental studies. Multimedia models were used to estimate the distribution and expected concentrations in environ-mental compartments at different distances from the source. Aerial transport parameters such as characteristic travel distances (CTD) were also derived. Existing monitoring data show that pendimethalin findings are highly correlated with time and location of application. The modelling results confirm that aerial transport of pendimethalin is possible over a few tens of kilometres whereas transport over longer distances to remote areas is unlikely. Mitigation of aerial transport is achieved with a new encapsulated CS formulation. A significant reduction of the volatilization rate of encapsulated pendimethalin compared with EC and SC formulations was shown in laboratory and wind tunnel (semi field) experiments where also the transport and deposition of pendimethalin was significantly reduced. Trace detections of pendimethalin in air can be further minimised by use of appropriate application techniques and avoiding application at unfavourable climatic conditions. Adjuvants that reduce the volatility of pendimethalin containing products are under evaluation.

MO238
A moni-modelling approach for risk management of pesticide at territorial level
A. Di Guardo, Universita degli Studi di Milano-Bicocca / Department of Earth and Environmental Sciences; A. Finizio, University Milano - Bicocca / Department of Environmental and Lanscape Sciences and Earth Sciences
In general, approaches used by water quality managers to preserve water bodies

from the risks associated to the use of Plant Protection Products (PPPs) fall within two categories: monitoring campaigns or predictive models. Both approaches show pro and cons. Monitoring programs are required in current EU regulations, as they are very useful to verify whether the concentration of chemicals exceed predetermined trigger values (i.e. for PPPs it is 0.1 µg/L in groundwater). On the other hand, they represent a single point in space and time (static), in a situation in which different dynamic processes act at the same time; consequently, they cannot be used to forecast the future state of the environment. On the other hand, predictive models are very useful to spatially represent the forecasted contamination starting from several sources on the territory. However, they rely on assumptions, mainly related to the parameterisation of the model inputs which could introduce biases and uncertainties in the spatial estimation of pesticide transport toward water resources. In our opinion, a new methodology that provides the integration of both approaches (what we here call moni-modelling approach) could provide invaluable help for risk managers. In fact, this approach would be very useful, particularly on a territorial scale, for a proper risk management of PPPs. In fact, it would be helpful to: a) identify sensible areas where implement mitigation measures or limitation of use, b) re-design future monitoring plans, c) better calibration of the pedo-climatic input data for the environmental fate models. As a case study, the proposed approach has been applied to Lombardy region (a NUTS 2 zone in North of Italy) using six active ingredients with different leaching behaviours.

MO239

The Wash-off Model - A new approach to estimate wash-off of biocides from different surfaces

B. Kind, WSC Scientific GmbH

Biocidal products can be applied outdoors on various surfaces like terraces, balconies, walls, fences, pavements etc. as a protection against insects or different herbs. These products can then be washed off by precipitation and reach soils and drainpipes. This route of entrance needs to be considered in the Environmental Risk Assessment of Biocides. Unfortunately, the proportion of the active substance washed off is rarely known so that complete wash-off immediately after application is often assumed as a worst-case. Since this is rather unrealistic, a wash-off model was developed for different surfaces, which calculates the amount washed off due to a known wash-off factor which has been the proposed procedure so far. Additionally, the amount can be estimated using the substance water solubility and the mean precipitation. The amount being washed-off may further be reduced by losses due to photodegradation and volatilization between the application and the first rainfall event. Relevant input parameters are the amount of active substance applied (mg/m^2 or mg/m), the area (m^2) or perimeter (m) of the outdoor surface based on the Emission Scenario Documents (ESDs) and, if possible, the volatilization rate (d^{-1}) and photodegradation half life (d) along with the time (d) between application and the first rainfall. If the last three parameters are not known, default values of 1000 days for photodegradation, 0 for volatilization rate and 0 days between application and rain are assumed as worst-case. For the established approach only the wash-off factor has to be entered in addition to the inputs mentioned above. For the alternative approach, the user has to enter the water solubility (mg/L) along with a mean rainfall amount (mm). Data on precipitation can be estimated using e.g. FOCUS scenarios from the current FOCUS models (e.g. FOCUS-PEARL 4.4.4, FOCUS-PELMO 5.5.3). The two approaches are demonstrated in a short example. A substance is applied with the amount of 10 mg/m^2 on a 30 m^2 area, resulting in 300 mg a.s. applied and washed off when using a worst-case wash-off factor of 1. But due to its low solubility of 1 mg/L and assuming a mean rainfall of 4 mm, the actual amount washed off during the next rain event is reduced to 120 mg a.s. In conclusion, the wash-off model can help to estimate realistic wash-off amounts of biocidal products from outdoor surfaces, either based on a given wash-off factor or on the water solubility of the active substance.

MO240

Outdoor use of Biocidal products: considering contaminated rainwater pathways in the urban context and potential for harmonisation

F. Ericher, CEA; S. Taylor, Cambridge Environmental Assessments
